A B S T R A C T

High-energy ball-milling is proven to be an effective technique for manufacturing reactive aluminum nanopowders. The procedure of milling presented in this work allows the elaboration of aluminum powders with specific surface areas around 20 m²/g. The particles have platelet morphology and are constituted by a nanocrystalline aluminum core surrounded by a thick amorphous alumina layer of 4.5 ± 0.5 nm. The reactivity of the powders is enhanced as compared to nanopowders elaborated with techniques involving vapor phase condensation. The morphology, the microstructure and the initial thickness of the alumina layer are shown to be important parameters that influence the reactivity. The method could be extended to any other ductile metal, provided a hard surface layer is continuously formed during milling.

1. Introduction

Aluminum nanopowders (Al-NPs) are widely studied because of their applications as propellant rate modifiers, explosive additives and energetic microsystems [1,2]. In all those applications, it is the highly exothermic reaction of aluminum with an oxidant that confers to the powders their reactive and/or propulsive properties. Al-NPs can be defined as powders having specific surface areas higher than 10 m²/g. Each particle is constituted by a crystalline aluminum core covered by a thin amorphous alumina layer [1]. For low heating rates, a diffusion controlled mechanism is generally proposed to explain the oxidation mechanisms of Al-NPs. In that case, the oxidation of aluminum is stepwise and linked to the polymorphic transitions of the alumina shell [3]. The first oxidation step (around 550 °C), is related to the crystallization of the native amorphous layer into γ -alumina. The density increase of alumina upon crystallization leads to the breakage of the layer and the new as-formed bare aluminum zones immediately oxidize, explaining the increase of the oxidation rate. Because the reactivity of aluminum powders depends both on specific surface area and microstructural changes, it is interesting to test several elaboration methods in order to optimize both parameters. Until now, AL-NPs are manufactured either by vapor phase condensation or by liquid state chemistry [1]. In this paper a mechanical milling approach is proposed for the synthesis of highly reactive Al-NPs. Milling techniques are currently experiencing a revival for

the manufacturing of nanostructured powders with enhanced properties as compared to their bulk counterpart [4,5] but to our knowledge, they were up to now never used to optimize the reactivity of aluminum powders. Indeed, due to their ductility, it is very difficult to increase specific surface area higher than 16 m² g⁻¹ by this method [6]. In this contribution, we show that, thanks to a milling procedure in which air is introduced in a controlled way, it is possible to increase the specific surface area of the powders and to modify the microstructure of the aluminum particles.

2. Experimental details

Aluminum powder from Alfa Aesar (purity=99.8%) was used as the starting material. The milling was conducted with a high-energy planetary ball mill (P4 Fristch) using vials and balls in stainless steel in order to limit the amount of impurities [7,8]. The rotation speed of vials and plateau were respectively fixed to 800 rpm and 400 rpm, in opposite directions. Paraffin oil was added into the vials in order to minimize cold welding and to increase the efficiency of the milling [9]. For all samples, the total milling time was fixed to 16 h by alternating 10 min of milling and 30 min of rest in order to reduce the temperature increase inside the vials. A controlled quantity of air (71 cm³) was added once (MM-air-1), four times (MM-air-4), eight times (MM-air-8) and 16 times (MM-air-16). The first filling was done at the beginning of the milling; the others were done at equal time periods of milling, i.e. every 4 h, every 2 h and every hour for MM-air-4, MM-air-8 and MM-air-16, respectively. At the end of the procedure, the paraffin oil was removed as described in [10]. The purity of the

powders was checked by ICP analyses. In the following, these samples will be compared to other powders having a spherical morphology: a micronic powder from Hermillon poudres© (Micro-H), two nanopowders elaborated by wire electro explosion (WEE) and passivated either in air atmosphere (Nano-G) or in a liquid solution containing stearic acid (Nano-L) (see [11] for details).

Nitrogen adsorption-desorption isotherms were determined at 77 K using a commercial Autosorb-1 apparatus from Quantachrome.

Fig. 1. Specific surface area of the powders plotted as a function of the number of air introduction. The results are compared to spherical powders obtained by other elaboration processes.

Transmission electron micrographs were taken by an FEI Titan 80-300 transmission electron microscope equipped with an image corrector and working at an acceleration voltage equal to 300 kV. Standard TEM imaging was performed and, in order to suppress the contrast variations due to changes in crystallographic orientations, images were also taken in the STEM mode (STEM-HAADF). High resolution thermogravimetry measurements (HRTGA) were carried out under a dynamic dry air atmosphere (60 ml/min) with a TG Q-Series 500 from TA-Instrument.

3. Results and discussion

The adsorption-desorption isotherms are characteristic for a non-porous material and the BET equation was used to calculate the specific surface areas a_s . As presented in Fig. 1, milling without air renewal (MM-air-1) leads to powders with low specific surface area typical of micron-sized particles and comparable to the Micro-H powder. As soon as air is introduced during the milling the specific surface area increases to values higher than $10 \text{ m}^2/\text{g}$. After eight air fillings, the specific surface area obtained is around $20 \text{ m}^2/\text{g}$ which is much higher than the ones obtained for WEE powders [12]. Milling is thus an effective technique to synthesize Al-NPs. TEM image of Fig. 2a shows the platelet morphology of the particles, as expected from the ductility of aluminum and in agreement with previous studies [5,10]. The particles appear themselves as aggregates of smaller particles with poorly defined shapes and dimensions smaller than 100 nm as seen on the STEM-HAADF image (Fig. 2b). The particles are made of polycrystalline Al (Fig. 2c) surrounded by an amorphous layer with a thickness of $4.5 \pm 0.5 \text{ nm}$ (Fig. 2d). Amorphous alumina at the grain boundaries

Fig. 2. TEM images of the MM-air-16 sample. Platelet morphology is observed (a) and the particles are aggregated (b). The aluminum core is polycrystalline (c) and the amorphous alumina layer has a thickness around $4.5 \pm 0.5 \text{ nm}$ (d).

could not be evidenced (Fig. 2c). Interestingly, the thickness of the surrounding alumina layer is larger than the commonly reported value of 3 ± 0.5 nm for Al-NPs synthesized using other techniques [1,13,14] and it may be a consequence of the introduction of air during the milling.

Fig. 3 shows the HRTGA curves obtained for the milled powders and compared with other aluminum powders. The expected [1,3,10,13] stepwise oxidation is systematically observed for all the powders. Two values can be used to quantify and compare the reactivity of different powders: (i) the temperature T_1 at which the oxidation starts (defined as the inflexion point of the first step on the curve) and (ii) the mass gain after the first oxidation step M_1 . A powder with enhanced reactivity will be thus characterized by a lower T_1 and a higher M_1 as compared to the existing ones. As seen in Fig. 3, the temperature T_1 is continuously lowered by the addition of air during milling and reaches a value around 500 °C for the MM-air-16 powder. Moreover, milling under air leads to a stationary value of M_1 around 40% which is much higher than anyone obtained for the WEE powders. Finally, the platelet morphology seems advantageous for the mass gain: for micron-sized powders (MM-air-1 compared to Micro-H), the mass gain M_1 is higher for platelets than for spherical particles. The continuous decrease of T_1 with increasing the quantity of air during the milling can be explained by the formation, during the milling, of a thicker amorphous layer that reaches a value equal to 4.5 ± 0.5 nm for MM-air-16 sample (Fig.2d). Under oxidizing conditions, this layer reaches a critical value for crystallization at a lower temperature and the first oxidation step is advanced. This effect is probably enhanced by the polycrystalline nature of the aluminum core (Fig. 2c), since the critical thickness is dependent on the crystallographic orientation of the aluminum crystallites [15]. The decrease of T_1 could also be linked to the microstructure of the metallic core since grain boundary distribution is known to modify the properties of metals [16]. In the present study, it may increase the speed of diffusion species through the aluminum core. In the same way, the total mass increase at 880 °C diminishes with the quantity of air introduced which is also related to the introduction of air during the milling

that increases the quantity of alumina in disfavor to the total amount of metallic aluminum in the powder. This is a general result with Al-NPs: the higher the specific surface area the lower is the metallic content due to the existence of the alumina layer. For energetic applications, a compromise between reactivity (higher surface area) and energy release during combustion (high aluminum content) has to be found.

4. Conclusion

In summary we have proved that high-energy ball milling is an effective technique to synthesize reactive Al-NPs. The introduction of air during milling enables to obtain powders with high specific areas: the continuous regeneration of the alumina layer maintains the hardness of the powders which in turn can be more easily broken. The morphology and the microstructure of the aluminum core and the alumina shell are shown to be key parameters that directly influence the reactivity. High-energy ball milling could be used to tune the properties of the elaborated powders according to the desired mass increase or advanced oxidation. At last, the method could be extended to any other ductile metal, provided a hard surface layer is continuously formed during milling.

Acknowledgment

M. Dumont and J. Rogez (IM2NP) are acknowledged for fruitful discussions. TEM measurements were performed on the CIMPACA platform. SNPE is thanked for providing plasma and WEE samples. This work was granted by Institut Carnot STAR and C'Nano PACA.
