21 **Abstract**

22 Stable isotopes have been widely used to monitor remediation of environmental  
23 contaminants over the last decades. This approach gives a good mechanistic description  
24 of natural or assisted degradation of organic pollutants, such as methyl *tert*-butyl ether  
25 (MTBE). Since abiotic degradation seems to be the most promising assisted attenuation  
26 method, the isotopic fractionation associated with oxidation and hydrolysis processes  
27 need to be further investigated in order to understand better these processes and make  
28 their monitoring more efficient. In this study, position-specific isotope effects (PSIEs)  
29 associated with permanganate oxidation and acid hydrolysis of MTBE were determined  
30 using isotope ratio monitoring by <sup>13</sup>C Nuclear Magnetic Resonance (irm-<sup>13</sup>C NMR)  
31 combined with isotope ratio monitoring Mass Spectrometry (irm-MS). The use of this  
32 Position-Specific Isotopic Analysis (PSIA) method makes it possible to observe a specific  
33 normal IE associated with each of these two abiotic degradation mechanisms. The present  
34 work demonstrates that the <sup>13</sup>C isotope pattern of the main degradation product, *tert*-butyl  
35 alcohol (TBA), depends on the chemical reaction by which it is produced. Furthermore,  
36 this study also demonstrates that PSIA at natural abundance can give new insights into  
37 reaction mechanisms and that this methodology is very promising for the future of  
38 modeling the remediation of organic contaminants.

41 ether (MTBE) – abiotic degradation – remediation

42

## 43 1. Introduction

44 Monitoring *in situ* degradation and bioremediation of groundwater pollutants is a major  
45 environmental challenge in which Compound Specific Isotope Analysis (CSIA) is today a  
46 routine technique (Hofstetter and Berg 2011). Measuring the isotopic signature of a  
47 molecule gives information pertinent to determining its origin and fate, as already  
48 demonstrated in many areas of research: geochemistry, forensics, pharmacology and  
49 environmental sciences (Aelion et al. 2010). In most cases, CSIA is performed using  
50 isotope ratio monitoring by Mass Spectrometry (irm-MS) targeting mostly  $^{13}\text{C}$  and  $^2\text{H}$  in  
51 organic contaminants (Elsner et al. 2012; Thullner et al. 2012). This analytical technique  
52 can be used routinely to determine isotopic compositions of a large range of compounds  
53 with a high precision (SD for  $^{13}\text{C} \approx 0.3\text{‰}$ ) and requires only a small amount of product  
54 (about 1 mg depending on the chemical composition and the analyzed element). Irm-MS  
55 can also be applied to complex mixtures when coupled to Gas Chromatography (irm-GC-  
56 MS) or High Performance Liquid Chromatography (irm-LC-MS), an interfacing that also  
57 has the advantage that sub-mg quantities can be analyzed (Meier-Augenstein 1999;  
58 Godin and McCullagh 2011).

59 The inconvenience of irm-MS is that it only allows a bulk  $^{13}\text{C}$  isotope composition  
60 ( $\delta^{13}\text{C}_{\text{bulk}}$  in the case of carbon) to be measured, thus averaging all carbon positions of the  
61 molecule. Hence, valuable information about the  $^{13}\text{C}$  isotopic fractionation within  
62 molecules with numerous carbon atoms is diluted or lost completely (Bouchard et al.  
63 2008). Knowing only the average  $^{13}\text{C}$  isotopic composition value can be misleading when  
64 interpreting isotope effects (IEs); if  $\varepsilon_{\text{bulk}} \approx 0$ , does this mean that there is no fractionation  
65 or, rather, that there is a counteractive contribution of normal and inverse intramolecular

66 IEs at different positions? This conundrum can be resolved by Position-Specific Isotope  
67 Analysis (PSIA), which makes possible the discrimination of those isotopomers  
68 preferentially involved in a process when bulk isotope analysis only allows discriminating  
69 isotopologues (Coplen 2011). Measuring position-specific isotopic composition by  $^{13}\text{C}$   
70 Nuclear Magnetic Resonance (irm- $^{13}\text{C}$  NMR) is now a well-established technique  
71 (Jézéquel et al. 2017) employed over the last ten years to study plant metabolism (Gilbert  
72 et al. 2011, 2012), pharmaceutical origin (Silvestre et al. 2009) and, more recently,  
73 environmental contaminant remediation (Julien et al. 2015b, 2015a).

74 Methyl *tert*-butyl ether (MTBE) is a fuel oxygenate used as octane enhancer since the  
75 1970s to replace tetraethyl lead which is a Persistent organic pollutant (POP), toxic for  
76 living organisms. Despite its numerous advantages compared with lead derivatives,  
77 MTBE is soluble in water, meaning that it can travel faster and farther through soil and  
78 groundwater than other gasoline components (Johnson et al. 2000). For this reason it is  
79 one of the most encountered pollutants met in groundwater and, even if natural  
80 attenuation can be a solution, the corresponding accumulation of the metabolite *tert*-butyl  
81 alcohol (TBA) could be a more problematic pollution (see Figure 1 for the chemical  
82 structures of these compounds) (Kuder et al. 2005).

83 According to the literature, only a few position-specific isotopic fractionation studies  
84 have been performed on organic soil pollutants. Gauchotte *et al.* studied MTBE using  
85 Pyrolysis coupled with irm-MS (Py-GC-C-irm-MS) generating methanol and isobutene,  
86 thus losing a part of intramolecular information on the isobutene moiety (Gauchotte et al.  
87 2009). Some other partial intramolecular  $^{13}\text{C}$  isotopic composition determinations of soil  
88 pollutants have been performed using a chemical or enzymatic degradation before irm-

89 MS analysis (Huang et al. 1999). Pollutant removal has also been studied using isotopic  
90  $^2\text{H}$  NMR, but working on hydrogen or oxygen, which are exchangeable, is very different  
91 from observing  $^{13}\text{C}$  distribution which observes the skeleton of the organic analyte. Irm-  
92  $^{13}\text{C}$  NMR appears to be the only method currently able to directly determine the total  
93 intramolecular isotopic composition of Volatile Organic Compounds (VOCs) such as  
94 MTBE. In its initial development, it requires a larger amount of compound (around 200  
95 mg) but unlike (bio)chemical degradation and Py-GC-C-irm-MS, NMR it is not a  
96 destructive method so samples can be recovered.

97 MTBE is naturally removed from contaminated soil and groundwater through oxidation  
98 and acid hydrolysis reaction occurring in both soil and water. Different phenomena are  
99 involved in MTBE remediation and they all induce  $^{13}\text{C}$  and/or  $^2\text{H}$  isotopic fractionation.  
100 Kuder *et al.* demonstrated that  $^{13}\text{C}$  and  $^2\text{H}$  isotopic fractionation are induced by passive  
101 evaporation, with an inverse  $^{13}\text{C}$  IE appearing during the process (Kuder et al. 2009).  
102 Moreover, volatilization of VOCs has been proven to be associated with  $^{13}\text{C}$  position-  
103 specific isotopic fractionation (Julien et al. 2015b, 2015a). Isotopic fractionation in both  $^2\text{H}$   
104 and  $^{13}\text{C}$  have also been detected during MTBE biodegradation (Gray et al. 2002).  
105 However, as natural MTBE degradation is not effective enough for a fast total remediation,  
106 different technologies have been developed for the removal of MTBE (Levchuk et al.  
107 2014), such as air stripping (Sutherland et al. 2004), adsorption (Hung and Lin 2006),  
108 assisted biodegradation (Steffan et al. 1997) or electrochemical oxidation (Wu 2011).  
109 Advanced Oxidation Processes (AOPs) seem to be the most promising method to obtain  
110 a total mineralization of MTBE even if they can generate by-products which are  
111 themselves potentially toxic. Many studies have been done using Fenton reagent

112 (Burbano et al. 2005, 2008), persulfate (Huang et al. 2002; Huling et al. 2011) or acid  
113 hydrolysis (Elsner et al. 2007; Rosell et al. 2012) but oxidation of MTBE using  
114 permanganate seems to be the most promising *in situ* method to eliminate this  
115 contaminant from groundwater.

116 Oxidation of MTBE using potassium permanganate has been proven as a means to  
117 rapidly clean up groundwater (Damm et al. 2002). As with other processes, MTBE  
118 oxidation induces significant bulk normal  $^{13}\text{C}$  and  $^2\text{H}$  IEs (Elsner et al. 2007). The bulk  
119 isotopic fractionation ( $\Delta\delta^{13}\text{C}_{\text{bulk}}$ ) obtained during this reaction is similar to fractionation  
120 observed with bioremediation with some aerobic bacterial strains such as *Methylibium*  
121 *petroleiphylum* PM1 (Rosell et al. 2012). In this context, as the bulk isotope analysis does  
122 not allow the (bio)degradation reaction(s) involved in the remediation to be identified, PSIA  
123 using irm- $^{13}\text{C}$  NMR could be a valuable tool to determine which process(es) are involved  
124 by interpreting the measured changes in  $^{13}\text{C}$  distribution between the carbon positions.  
125 Furthermore, PSIA should be helpful in estimating the degree of MTBE remediation  
126 occurring by chemical oxidation in contaminated sites, since the position-specific isotopic  
127 fractionation is related directly to the mechanism of the process involved.

128 In this study, permanganate oxidation and acid hydrolysis of MTBE have been  
129 performed and the resulting TBA has been purified and the  $^{13}\text{C}$  distribution analyzed using  
130 irm-MS and irm- $^{13}\text{C}$  NMR. This data has been used to calculate position-specific  
131 enrichment factors ( $\epsilon_i$ ) so as to obtain more precise information on the mechanism of these  
132 processes. Determined IEs associated with both acid hydrolysis and permanganate  
133 oxidation were then used to design models to observe the evolution of  $^{13}\text{C}$  intramolecular

134 isotopic composition of MTBE and generated products and their concentration during  
135 these two abiotic degradation processes (see attached Excel worksheets).

## 136 **2. Materials and Methods**

### 137 2.1. Chemicals

138 Methyl *tert*-butyl ether (99.8%), potassium permanganate ( $\geq 99.8\%$ ) and sulfuric acid  
139 (96%) were obtained from Sigma-Aldrich, sodium thiosulfate ( $\geq 97\%$ ) and tris(2,4-  
140 pentadionato)chromium(III) [Cr(Acac)<sub>3</sub>] were purchased from Merck, and DMSO-d<sub>6</sub> and  
141 acetonitrile-d<sub>3</sub> from Eurisotop.

### 142 2.2. Degradation experiments

143 Both abiotic degradations were performed in a 1 L round bottom flask. MTBE was  
144 oxidized in 600 mL of an aqueous solution of 100 mM potassium permanganate or  
145 hydrolysis was carried out using 500 mL of 250 mM aqueous sulfuric acid. The round  
146 bottom flask was closed with a turn-over flange stopper (in order to avoid MTBE  
147 evaporation) and 20 mL of pure MTBE were injected. Reactions were performed at room  
148 temperature (20-25°C) under stirring. Then, reactions were stopped by adding one  
149 equivalent (of the initial oxidant or acid) of sodium thiosulfate (100 mL at 0.6 M) or sodium  
150 hydroxide (100 mL at 1.25 M) to the oxidation or hydrolysis mixture, respectively.  
151 Afterwards, mixtures were distilled using a spinning band distillation column to purify the  
152 TBA generated by degradation, the remaining MTBE (and the generated methanol in the  
153 case of hydrolysis). A small amount (50  $\mu$ L) of the distillate was employed to determine  
154 the reaction yield using <sup>1</sup>H NMR; reaction yields of 13.8% and 29.8% were measured for  
155 permanganate oxidation and acid hydrolysis, respectively. Then, remaining MTBE (and

156 methanol) were eliminated from the distillate by nitrogen purging. Finally, TBA samples  
157 (containing about 35% of water) were analyzed by irm-EA-MS and irm-<sup>13</sup>C NMR.

158 To measure the bulk isotope fractionation with irm-MS in MTBE, both permanganate  
159 oxidation and acid hydrolysis were also performed under supposedly equal conditions but  
160 on a smaller scale than the large-volume experiments described above. Oxidation was  
161 done in a 20 mL vial where 0.3 mL of MTBE was dissolved in 15 mL of water. After  
162 equilibration of the mixture (under stirring), 1.33 g of KMnO<sub>4</sub> were added. Acid hydrolysis  
163 was also performed in a 20 mL vial in which 0.6 mL MTBE and 0.21 mL concentrated  
164 sulfuric acid were dissolved in 15 mL water (final pH = 0.48). The two reactions were  
165 performed at room temperature. Headspace gas (0.1 mL) was sampled every hour after  
166 heating the vials at 60° C for 7 min, in order to determine δ<sup>13</sup>C of the remaining MTBE.

### 167 2.3. Isotope ratio monitoring by Mass Spectrometry (irm-MS)

168 The bulk <sup>13</sup>C isotopic composition (δ<sup>13</sup>C<sub>bulk</sub>) was determined by irm-MS as described  
169 previously (Julien et al. 2015a). Determination of δ<sup>13</sup>C<sub>bulk</sub> was performed using an Integra2  
170 spectrometer (Sercon Instruments, Crewe, UK) linked to a Sercon elemental analyzer  
171 (EA) (Sercon Instruments, Crewe, UK) for large scale experiments. About 1 mg of each  
172 sample was weighed into tin capsules (2x5 mm, Thermo Fisher scientific) using a 10<sup>-6</sup> g  
173 precision balance (Ohaus Discovery DV215CD) in order to ensure analysis of 0.2-0.8 mg  
174 of carbon. Bulk <sup>13</sup>C isotope analysis of MTBE samples from headspace of 20 mL vial  
175 reactions was performed using a Delta V advantage (Thermo Fisher Scientific) connected  
176 to a Gas Chromatography (Trace 1310, Thermo Fisher Scientific) equipped with a TG-  
177 5MS column (60 m x 0.25 mm i.d., 0.25 μm film thickness, Thermo Fisher Scientific) via a

178 CONFLOW-II interface.  $\delta^{13}\text{C}_{\text{bulk}}$  (‰) values were expressed relative to the international  
179 reference (Vienna-Pee Dee Belemnite, V-PDB) using the equation 1:

$$180 \quad \delta^{13}\text{C}_{\text{g}} (\text{‰}) = \left( \frac{R_{\text{sample}}}{R_{\text{standard}}} - 1 \right) \times 1000 \quad (1)$$

181 For  $\delta^{13}\text{C}_{\text{bulk}}$  determination, the laboratory standard of glutamic acid used for irm-EA-MS  
182 and the  $\text{CO}_2$  reference gas for irm-GC-MS analyses were calibrated against the  
183 international reference material.

#### 184 2.4. Isotope ratio monitoring by $^{13}\text{C}$ Nuclear Magnetic Resonance spectrometry (irm- 185 $^{13}\text{C}$ NMR)

186 The position-specific  $^{13}\text{C}$  isotopic composition ( $\delta^{13}\text{C}_i$ , where  $i$  is the corresponding  
187 carbon position) was determined as described previously (See Supporting Information for  
188 more details) (Julien et al. 2015b). The TBA sample was prepared in a 4 mL vial in which  
189 100  $\mu\text{L}$  of the lock substance ( $\text{DMSO-d}_6$ ) containing 50 mM of the relaxing agent  $\text{Cr}(\text{Acac})_3$   
190 were introduced.  $\text{DMSO-d}_6$  was chosen because of its miscibility with TBA and water and  
191 to avoid peak overlapping on the  $^{13}\text{C}$  spectrum between the sample and the deuterated  
192 solvent. The amount of  $\text{Cr}(\text{Acac})_3$  was adapted according to the  $T_1$  values (longitudinal  
193 relaxation). Then, 600  $\mu\text{L}$  of sample are added and, after mixing, the sample was  
194 introduced into a 5 mm NMR tube. MTBE NMR measurements were performed in the  
195 same way but with the following sample preparation: 500  $\mu\text{L}$  of MTBE mixed with 200  $\mu\text{L}$   
196 of acetonitrile- $\text{d}_3$  containing 200 mM of  $\text{Cr}(\text{Acac})_3$ .

197  $^{13}\text{C}$  NMR spectra of both MTBE and TBA were recorded using a Bruker AVANCE I 400  
198 MHz spectrometer fitted with a 5 mm i.d.  $^1\text{H}/^{13}\text{C}$  dual<sup>+</sup> probe, carefully tuned at the

199 recording frequency of 100.61 MHz. Detailed explanation of the isotopic  $^{13}\text{C}$  NMR protocol  
200 and  $\delta^{13}\text{C}_i$  calculation is available in Supporting Information.

## 201 2.5. Determination of enrichment factors ( $\epsilon$ )

202 For large scale degradation experiments,  $^{13}\text{C}$  Isotope Effects associated with both  
203 permanganate oxidation and acid hydrolysis were calculated using the  $t_0$  value and a  
204 single data point. This method of calculating the enrichment factor has already been  
205 shown to provide very similar results to the classical Rayleigh plot method which requires  
206 multiple data points (Jeannotat and Hunkeler 2012). Moreover, a recently published study  
207 has demonstrated that this “two point calculation” ( $t_0$  and one experimental point) gives  
208 the same result as a Rayleigh plot when less than 30% of MTBE has reacted (Julien et al.  
209 2018). In order to quantify bulk and position-specific enrichment factors, the equation 2,  
210 adapted from that work, has been used in the present work:

$$211 \quad \epsilon = \frac{\delta^{13}\text{C}_{\text{MTBE}} - \delta^{13}\text{C}_{\text{TBA}}}{\left(\frac{f}{1-f}\right) \times \ln} \quad (2)$$

212 where  $f$  is the reaction yield,  $\delta^{13}\text{C}_{\text{MTBE}}$  is the bulk ( $\delta^{13}\text{C}_{\text{Bulk}}$ ) or position-specific ( $\delta^{13}\text{C}_i$ )  
213 isotopic composition of MTBE used as reactant in abiotic degradation experiments and  
214  $\delta^{13}\text{C}_{\text{TBA}}$  is the bulk ( $\delta^{13}\text{C}_{\text{Bulk}}$ ) or position-specific ( $\delta^{13}\text{C}_i$ ) isotopic composition of TBA. When  
215  $\epsilon_i$  (position-specific enrichment factor) is calculated, the  $\delta^{13}\text{C}_i$  of the corresponding carbon  
216 position is used for both MTBE and TBA. In this calculation, the bulk  $\delta^{13}\text{C}_{\text{MTBE}}$  cannot be  
217 used directly in the calculation but the average value of the quaternary carbon and the  
218 methyl groups of MTBE (corresponding to the carbon atoms of the reaction product, TBA  
219 see Figure 1) need to be used in order to calculate the bulk IE associated with the

220 generation of TBA from MTBE. When  $\varepsilon$  is negative, the IE is considered as normal (light  
221 isotopologues are preferentially used during the process) and when  $\varepsilon$  is positive, the IE is  
222 inverse (transformation is faster for heavy isotopologues).

223 In the case of smaller scale experiments,  $\delta^{13}\text{C}$  of MTBE was monitored using irm-GC-  
224 IRMS. In this context, Rayleigh plots ( $1000 \cdot \ln(\delta+1000)/(\delta_0+1000)$ ) vs  $\ln(f)$  were drawn  
225 and  $\varepsilon$  corresponds to the slope of the regression curve (see Figure S3 in the Supporting  
226 Information).

227 Finally, in order to determine the significance threshold of the measured enrichment  
228 factors, the expanded uncertainty (U) has been calculated. The calculation of U  
229 associated with  $\varepsilon$  takes into account all sources of uncertainty generated by weighing of  
230 compounds or the measurement of the reaction yield. While most studies only use the  
231 standard deviation (SD) of the isotopic measurement, U gives a better assessment of  
232 accuracy. The calculation of U has been fully described in a previous study (Julien et al.  
233 2018) and results are expressed as  $\varepsilon \pm U$  in this article (note that results from cited articles  
234 are expressed as  $\varepsilon$  or  $\Delta\delta^{13}\text{C} \pm 1\text{SD}$ ).

235 2.6. Position-specific modeling of isotope ratios A model for the temporal  
236 evolution of the isotope ratio at each specific position during the reaction of MTBE was  
237 developed based on equations which were published previously (Höhener et al, 2017).  
238 The model was modified in the sense that no transport in a groundwater system is  
239 included, but it was extended in order to include the isotope evolution of the formed  
240 products as well. The model is an Excel spreadsheet and is provided in Appendix A. A  
241 detailed description of all model equations is included in this spreadsheet.

242 **3. Results and discussion**

243 3.1. Reaction rates and bulk isotope analysis

244 The change in concentration of MTBE for both abiotic transformation reactions  
245 followed a first-order type kinetics, with half-life times of 0.33 and 5.7 per day for  
246 permanganate oxidation and hydrolysis, respectively. These rates are similar to previously  
247 published rates (Elsner et al., 2007; Gauchotte et al., 2009). The monitoring of the bulk  
248 MTBE <sup>13</sup>C isotope enrichment allowed  $\epsilon$  values of  $-4.9 \pm 0.2\text{‰}$  and  $-6.4 \pm 0.6\text{‰}$  (see Table  
249 1) to be obtained for permanganate oxidation and acid hydrolysis, respectively, which is  
250 also in accordance with previous data found in the literature. In previous studies, Rosell  
251 et al. 2012 described  $\epsilon$  values of  $-5.5 \pm 0.1\text{‰}$  and  $-6.1 \pm 0.1\text{‰}$  for permanganate oxidation  
252 and acid hydrolysis respectively, Elsner et al. 2007 measured  $\epsilon$  of  $-4.9 \pm 0.2\text{‰}$  associated  
253 with acid hydrolysis and Gauchotte et al. 2010 determined  $\epsilon$  of  $-4.9 \pm 0.6\text{‰}$  in the case of  
254 permanganate oxidation (see Table 1).

255 In the present study, the bulk isotope effect was also monitored using the product of the  
256 reaction, TBA. The present study shows that large scale permanganate oxidation and acid  
257 hydrolysis are both associated with a normal bulk <sup>13</sup>C IE according to their  $\epsilon$  values of -  
258  $1.9 \pm 0.7\text{‰}$  and  $-3.8 \pm 0.7\text{‰}$  obtained from the product TBA, respectively (see Table 1).  
259 Note that most isotope fractionation studies found in literature are performed analyzing  
260 the remaining substrate, but in this study the reaction product was also analyzed.  
261 However, it must be noted that TBA is not the only product (the methyl carbon left) and  
262 therefore it is logical that the value for the isotope effect obtained from the product does  
263 not relate directly to the value obtained from the substrate.

264        Nonetheless, the results all agree that the abiotic degradation velocity is higher with  
265 light MTBE isotopologues (molecules containing  $^{12}\text{C}$  isotope) (Bigeleisen 1949), in  
266 accordance with the principles of reaction rate theory in the presence of heavy isotopes  
267 (Haring 1942). Since a  $^{13}\text{C}$ – $^{12}\text{C}$  bond is shorter than a  $^{12}\text{C}$ – $^{12}\text{C}$  bond and the vibrational  
268 energy of shorter bonds is smaller (lower zero point energy), the activation energy needed  
269 to break a  $^{13}\text{C}$ – $^{12}\text{C}$  bond is higher than for a  $^{12}\text{C}$ – $^{12}\text{C}$  bond. In the conditions studied,  
270 abiotic degradation of MTBE apparently preferentially uses light substrate, as normal IEs  
271 are detected.

### 272        3.2. Position-specific isotope analysis – oxidation

273        In the present work, PSIA performed using isotopic  $^{13}\text{C}$  NMR showed an unbalanced  
274 distribution of normal IEs associated with MTBE oxidation by potassium permanganate.  
275 Despite a relatively small  $\delta^{13}\text{C}_{\text{Bulk}}$  it is found that this abiotic degradation process is  
276 associated with a strong normal IE on the quaternary carbon ( $\varepsilon = -10.1 \pm 0.7\text{‰}$ ) and  
277 negligible IEs on the methyl groups ( $\varepsilon = +0.8 \pm 0.7\text{‰}$ , see Table 1). The degradation  
278 mechanism of oxidation of MTBE by potassium permanganate has been described  
279 previously (for a detailed description, see Figure 2) (Damm et al. 2002; Elsner et al. 2007)  
280 and it is considered that it is initiated by H abstraction from the methyl of the methoxy  
281 group, leading to oxidation and bond breakage via an  $\text{S}_{\text{N}}2$  reaction mechanism. This  
282 reaction scheme is compatible with both the observed high secondary normal IE on the  
283 quaternary carbon, which is in  $\alpha$  position to the broken bond, and the absence of  
284 significant IE on the methyl groups, which are inert during the degradation mechanism.  
285 This theory is confirmed by results of the present study and those from Gauchotte *et al.*  
286 (2009) who determined the  $^{13}\text{C}$  isotopic fractionation ( $\Delta\delta^{13}\text{C}$ ) occurring during MTBE

287 oxidation using pyrolysis coupled with GC-C-irm-MS. This method allowed the  
288 observation of the isotopic composition of the methoxy group and an average value of the  
289 central carbon and methyl positions of MTBE. These experiments showed a large  $^{13}\text{C}$   
290 enrichment in the methoxy group and no significant change in  $^{13}\text{C}$  isotopic composition of  
291 other carbon positions of the remaining MTBE. Results from these studies demonstrate  
292 that the bond breaking (between the oxygen atom and the methoxy group) occurring  
293 during permanganate oxidation of MTBE is associated with a primary normal  $^{13}\text{C}$  IE on  
294 the methoxy group and a strong secondary normal  $^{13}\text{C}$  IE on the quaternary carbon  
295 position.

### 296 3.3. Position-specific isotope analysis – hydrolysis

297 In the case of acid hydrolysis, irm- $^{13}\text{C}$  NMR analysis indicates a very different  
298 distribution of the  $\delta^{13}\text{C}_i$  values contributing to the observed  $\delta^{13}\text{C}_{\text{Bulk}}$  normal IE to that of  
299 permanganate oxidation. Acid hydrolysis catalyzed by sulfuric acid is associated with a  
300 normal IE distributed between the quaternary carbon ( $\varepsilon = -3.2 \pm 0.7\text{‰}$ ) and the methyl  
301 groups ( $\varepsilon = -4.0 \pm 0.7\text{‰}$ ), see Table 1. Measuring different PSIEs is not surprising, given  
302 that the mechanism of reaction is considered to be very different from that of  
303 permanganate oxidation (see Figure 2). In the hydrolysis reaction, the bond between the  
304 oxygen atom and the quaternary carbon is broken, which fits with the observed large  
305 primary  $^{13}\text{C}$  IE located at this carbon position. Elsner *et al.* (2007) demonstrated that acid  
306 hydrolysis is associated with a large normal IE and calculated an  $\varepsilon$  value for the central  
307 carbon position ( $\varepsilon = -24.3 \pm 2.3\text{‰}$ ), assuming that all other carbons do not enrich (Table  
308 1) (Elsner *et al.* 2007). The most surprising result here is the presence of secondary  
309 normal IEs located on the methyl groups, however, because this part of the MTBE

310 structure is supposed not to be involved in the initial bond breaking reaction. Our results  
311 show that the effect on the reactive position is smaller, as assumed by Elsner and co-  
312 workers. However, acid hydrolysis is an S<sub>N</sub>1 reaction, with a carbocation intermediate (see  
313 Figure 2) and the normal IE located on the methyl groups can be proposed as due to the  
314 stabilization process of this intermediate state. As a consequence, the presence of a <sup>13</sup>C  
315 isotope on methyl groups could affect the stability of the carbocation intermediate and aid  
316 these isotopomers to react faster during bond breaking between the quaternary carbon  
317 and the oxygen atom.

318 As explained above (section 3.1.), <sup>13</sup>C–<sup>12</sup>C bonds are more difficult to break than <sup>12</sup>C–  
319 <sup>12</sup>C, because chemical bonds involving heavy isotopes have a lower zero-point energy  
320 and the activation energy required for bond breaking is greater, so heavy isotopomers are  
321 more stable than light ones. According to this convention, the presence of a <sup>13</sup>C isotope  
322 at the methyl positions of MTBE molecules could play a role in the stabilization of the  
323 transition-state (carbocation) during the acid hydrolysis of MTBE (Figure 2). As a  
324 consequence, MTBE molecules with <sup>12</sup>C on their methyl positions (light isotopomers)  
325 should react faster, while heavy isotopomers form more stable carbocation intermediates.  
326 This carbocation stability difference can explain the detection of a normal secondary  
327 isotope effect on these carbon positions. This precept has already been described in the  
328 case of enzyme catalytic activity in which the presence of heavy isotopes influences the  
329 stability of the transition-state and is directly responsible for the IEs associated with  
330 enzyme activity (Schramm 1998).

331 3.4. Modeling MTBE abiotic degradation

332 Bulk carbon isotopes are employed for (i) detecting the origin of organic contaminants, (ii)  
333 monitoring their natural or assisted remediation until their complete mineralization and (iii)  
334 understanding the mechanisms involved. The use of PSIA has already proved to be an  
335 efficient tool to determine the origin of organic contaminants such as VOCs (Julien et al.  
336 2016) or pharmaceuticals (Silvestre et al. 2009). This method offers more parameters to  
337 identify the origin of detected pollutants compared with bulk isotope analysis, which only  
338 allows one  $\delta^{13}\text{C}$  value to be determined. Moreover, PSIA has also proved its capability to  
339 detect unexpected intramolecular IEs associated with VOCs evaporation (Julien et al.  
340 2015b, 2015a) and, more generally, effects caused by the presence of non-covalent  
341 interactions (Botosoa et al. 2008; Julien et al. 2017).

342 In the present study, PSIEs associated with two abiotic degradation reactions (oxidation  
343 and acid hydrolysis) of MTBE were measured. These new data strengthen our  
344 fundamental understanding of these processes by validating the two different  
345 mechanisms previously proposed in the literature (Elsner et al. 2007). A highlight of this  
346 study is the construction of a model capable of predicting isotope ratios of MTBE carbon  
347 positions as a function of time during abiotic degradation (here, acid hydrolysis or  
348 oxidation). This new model requires the measurement of the initial  $^{13}\text{C}$  distribution in  
349 MTBE and the PSIEs measured in this article (see blue boxes in Appendix A). The initial  
350 MTBE concentration, the degradation half time and the duration of reaction can be  
351 adjusted in the Excel worksheet. Figure 3 presents the evolution of  $\delta^{13}\text{C}$  on both degraded  
352 MTBE and formed TBA carbon positions. The development of this model can help  
353 predicting the isotope changes in MTBE along a contaminant plume of gasoline in

354 groundwater or soil using the 3-dimensional transport code BIOSCREEN-AT-ISO  
355 (Höhener et al. 2017).

#### 356 **4. Conclusions**

357 PSIA performed using irm-<sup>13</sup>C NMR is still considered as difficult to apply for field  
358 investigations because of the amount of sample needed for each analysis. However, it  
359 has recently been shown that PSIA by NMR can be performed with less than 50 mg, and  
360 analysis of samples of the order of 10 mg is in advanced development (Joubert et al.  
361 2018). Hence, PSIA by <sup>13</sup>C NMR targeting TBA could be an excellent tool for mechanism  
362 elucidation and modeling of natural processes, such as environmental contaminant  
363 remediation. PSIA is shown to give a more detailed picture of the isotopic fractionation  
364 during abiotic remediation processes, distinguishing which isotopomers are preferentially  
365 involved in the reaction system. The determination of position-specific isotopic  
366 composition provides a more detailed dataset, crucially, one that indicates which  
367 mechanism of reaction was involved in the degradation. Thus, it can act as a useful  
368 indicator of which remediation processes may be dominant during the remediation of an  
369 organic pollutant, such as MTBE. As already explained, permanganate oxidation and acid  
370 hydrolysis of MTBE are both associated with a similar normal bulk IE, which does not give  
371 access to detail of the observed abiotic degradation process. In contrast, PSIA shows a  
372 large variation of the IE distribution between the two studied reactions, which means that  
373 the different processes involved in remediation can be distinguished by using the  
374 measured intramolecular <sup>13</sup>C isotope signatures, thus offering a new tool to monitor  
375 contaminant removal. Intramolecular IEs measured *in vitro* using irm-<sup>13</sup>C NMR combined  
376 with designed models predicting the evolution of <sup>13</sup>C distribution in MTBE and its

377 degradation products (see attached Excel worksheet) is a new efficient tool for monitoring  
378 soil contamination by gasoline-derived pollutants.

379 Complementary investigations are now required to underpin the interpretation of these  
380 observed position-specific IEs in terms of the proposed reactions mechanisms. The  
381 determination of  $^{18}\text{O}$  IEs would be of interest, as these should differ considerably between  
382 the permanganate oxidation and acid hydrolysis, because the oxygen atom of TBA comes  
383 from MTBE in the case of oxidation while it is added from water during acid hydrolysis  
384 (Figure 2). This, however, requires purifying the TBA from water without introducing  
385 isotopic fractionation. Theoretical calculations should also help to relate the observed IEs  
386 to mechanism (Wolfsberg et al. 2009), but these have proved challenging and are beyond  
387 the scope of the present report. It is evident that PSIA gives new clues about  
388 environmental contaminant removal and can be used for modeling, as already shown in  
389 the case of tetrachloroethene (Höhener and Atteia 2014). The constant improvement in  
390 terms of sensitivity, precision and complexity of analyzed structures of PSIA techniques,  
391 including more sensitive irm- $^{13}\text{C}$  NMR (Jézéquel et al. 2017), Py-GC-C-irm-MS (Gilbert et  
392 al. 2016) and the recent proof of concept for high resolution MS (Eiler et al. 2017) assure  
393 that PSIA can be an excellent tool for the future of monitoring of organic contaminant  
394 remediation.

	MTBE	TBA	<i>i</i> -Butylene	Methanol		
permanganate oxidation	+6.2 ± 0.2	-	0.0 ± 0.4	+22.8 ± 0.5	Gauchotte et al. 2009	

549  
550 **Table 1:** Comparison of enrichment factors ( $\epsilon$ ) associated with permanganate oxidation  
551 and acid hydrolysis of MTBE determined in this study and values found in literature (C(IV)  
552 corresponds to the quaternary carbon of MTBE). Position-specific isotope data from  
553 Gauchotte et al. 2010<sup>33</sup> are expressed as isotopic fractionation ( $\Delta\delta^{13}\text{C}$ ), so they are  
554 detailed in a separated table below.

555 <sup>a</sup>: Calculated through mass balance.

556 <sup>b</sup>: Theoretical value if no secondary isotope effects on other carbons.

557

558

559

560 **Figure 2:** Proposed reaction mechanisms of MTBE degradation during (a) potassium

561 permanganate oxidation and (b) acid hydrolysis. The symbol “-” indicates the carbon

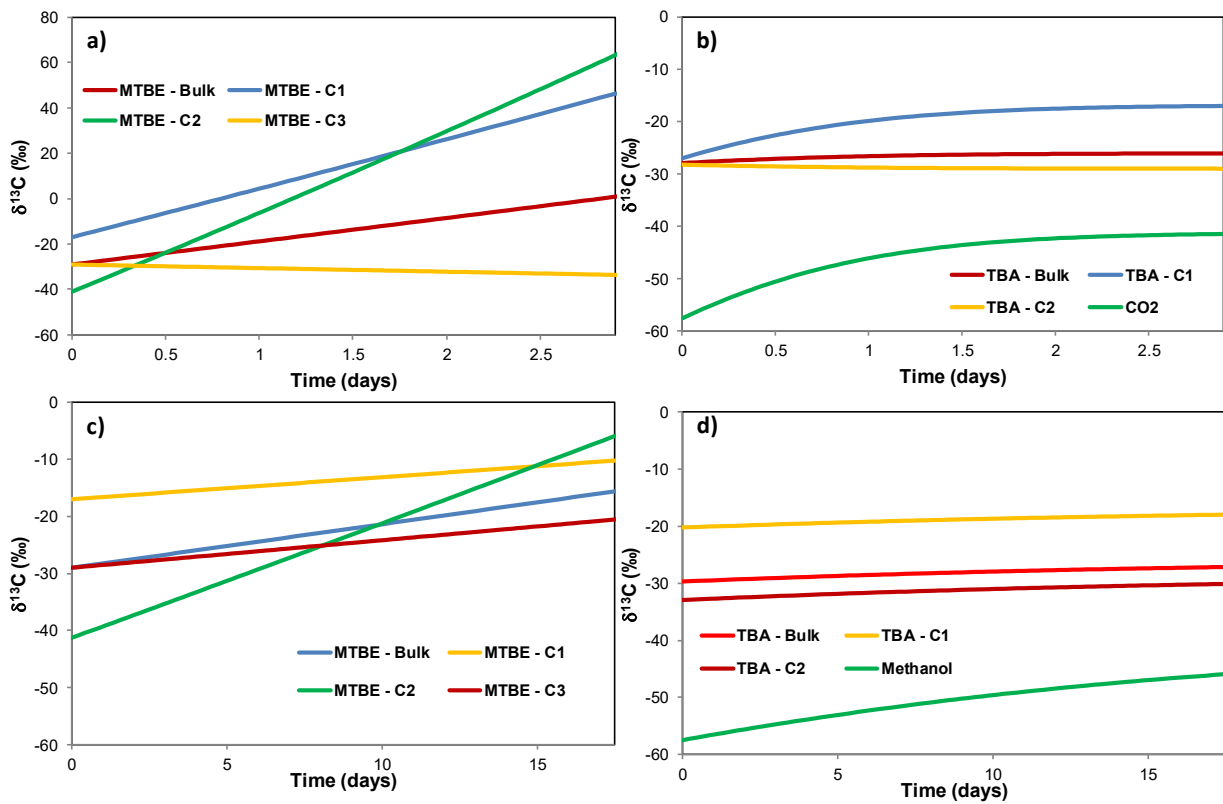

562 positions where a significant normal isotope effect was measured.

563

564

565

566

567

568 **Figure 3:** Evolution of  $\delta^{13}\text{C}$  as a function of time during permanganate oxidation (a: MTBE;

569 b: reaction products) and acid hydrolysis (c: MTBE; d: reaction products). The calculations

570 were carried out using the model developed in the present study.
