24 **Funding**

25 This study was funded mainly by the ANSES in the ETNA2 project context, by a grant of the University of Lille
26 and the SMRE doctoral school and by a public grant overseen by the French National Research Agency (ANR)
27 as part of the French platform NanoID (EQUIPEX project ANR-10-EQPX-39-01).

31 ABSTRACT

32

33 The use of silver nanoparticles (AgNPs) in agriculture and many consumer products has led to
34 significant release of Ag in the environment. Although Ag toxicity in terrestrial organisms has been studied
35 extensively, very little is known about the accumulation capacity and coping mechanisms of organisms in Ag-
36 contaminated soil. In this context, we exposed *Eisenia fetida* earthworms to artificial OECD soil spiked with a
37 range of concentrations of Ag (AgNPs or AgNO₃). The main aims were to (1) identify the location and form of
38 accumulation of Ag in the exposed earthworms and (2) better understand the physiological mechanisms involved
39 in Ag detoxification. The results showed that similar doses of AgNPs or AgNO₃ did not have the same effect on
40 *E. fetida* survival. The two forms of Ag added to soil exhibited substantial differences in speciation at the end of
41 exposure, but the Ag speciation and content of Ag in earthworms were similar, suggesting that biotransformation
42 of Ag occurred. Finally, 3D images of intact earthworms obtained by X-ray micro-computed tomography
43 revealed that Ag accumulated preferentially in the chloragogen tissue, coelomocytes and nephridial epithelium.
44 Thus, *E. fetida* bioaccumulates Ag, but a regulation mechanism limit its impact in a very efficient manner. The
45 location of Ag in the organism, the competition between Ag and Cu, and the speciation of internal Ag suggest a
46 link between Ag and the thiol-rich proteins that are widely present in these tissues, most probably
47 metallothioneins, which are key proteins in the sequestration and detoxification of metals.

53 1. INTRODUCTION

54 Due to advances in nanotechnology and the increasing use of nanomaterials, metallic silver
55 nanoparticles (AgNPs) are an emerging contaminant in the terrestrial environment (McGillicuddy et al., 2017).
56 The incorporation of AgNPs in consumer products is increasing due to their unique properties, particularly their
57 antimicrobial effects (Vance et al., 2015). Most silver (Ag) release occurs in municipal wastewater, and
58 wastewater treatment plants allow efficient sequestration of Ag in sewage sludge (Kaegi et al., 2011). However,
59 the Ag species trapped in these biosolids are subsequently spread on agricultural soil when sludge is recycled as
60 fertilizer (Usman et al., 2012). A number of studies have shown that metallic Ag is transformed mostly into
61 silver sulfide (Kaegi et al., 2013; Ma et al., 2014) and silver bound to thiols in the sewage system. This
62 transformation strongly affects the behavior of Ag in the environment (Levard et al., 2012; Pradas del Real et al.,
63 2017).

64 Another potential environmental exposure scenario in terrestrial ecosystems is the use of Ag as a
65 nanopesticide or nanofertilizer via the direct application of metallic Ag to agricultural soils. Ag has bactericidal,
66 fungicidal, insecticidal and herbicidal properties, and AgNPs have high inhibitory activity against crop
67 pathogens (Chhipa, 2019; Khan and Rizvi, 2017). Moreover, AgNPs positively impact root elongation and the
68 general growth of cultivated plants (Chhipa, 2019) when applied at concentrations between 1 and 200 ppm,
69 depending on the plant species. However, at these concentrations, AgNPs are toxic to a variety of organisms.

70 The toxicological effects of AgNPs are quite well documented and include numerous impacts on soil
71 microflora, flora and soil invertebrates (Courtois et al., 2019). The potential transfer of Ag in plants has received
72 more attention (Yan and Chen, 2019) than transfer of Ag in animals. Most studies in animals have focused on
73 life traits and protein changes in exposed animals (Yu et al., 2013). Although accumulation of Ag could be an
74 important vector of the transfer of this metal in the trophic chain, studies of the underlying mechanisms are
75 scarce.

76 In soil ecotoxicology, earthworms are widely studied based on their key role in most continental
77 ecosystems and importance in the soil macrofauna. Earthworms participate in the maintenance of soil structure
78 and fertility. In addition to enriching the soil with organic matter available for plants, they aerate the soil and
79 promote water penetration by forming galleries during their burrowing activity (Bernard et al., 2010; Carbonell
80 et al., 2009). Earthworms are highly consumed by birds, snakes, insectivorous mammals and rodents, especially
81 during tillage. Consequently, accumulated contaminants can quickly move to upper trophic levels.

82 Studying Ag accumulation/defense mechanisms requires comprehensive knowledge of Ag distribution
83 and speciation. In the present study, we investigated the accumulation, localization, and speciation of Ag
84 (presented as NM-300K AgNPs or AgNO₃) in earthworms using several X-ray techniques. The main objective
85 was to better understand how earthworms cope with Ag soil contamination in the context of silver
86 pesticide/fertilizer use. For this purpose, *Eisenia fetida* earthworms were exposed to artificial OECD soil
87 contaminated with a range of AgNP concentrations for 4 weeks. The effect of ionic Ag (AgNO₃) was
88 investigated as a positive control. Biomass and mortality were followed, and Ag accumulation, speciation and
89 localization in earthworms were measured. Finally, the accumulation mechanisms are discussed.

90

91 **2. MATERIALS AND METHODS**

92 *2.1 Test species*

93 Genetically identified *Eisenia fetida* earthworms (Homa et al., 2015) from the laboratory breeding
94 facility (LGCgE, University of Lille) were fed cow manure *ad libitum*. Adult earthworms, clitellated or not, were
95 randomly selected and introduced into the microcosms after being weighed individually. The earthworms
96 weighed 296 mg on average (min: 104 mg, max: 751 mg, mean standard deviation: 95 mg).

97

98 *2.2. Soil*

99 Artificial soil was prepared for this experiment according to OECD guideline n° 207 (OECD, 1984) and
100 contained 10% sphagnum peat moss, 20% kaolin clay and 70% quartz sand. The soil pH was adjusted with
101 calcium carbonate to 6 ± 0.5 . Five weeks before adding the contaminant, 16.5 kg of soil was moistened with 6
102 liters of demineralized water. When the earthworms were added to the soil, water represented 27% of the weight
103 of the wet soil.

104

105 *2.3. Silver species*

106 The standard reference material Ag-NM300K from the European Commission Joint Research Centre
107 (JRC) was used as the AgNP source and was fully characterized in a previous work (Klein et al., 2011).
108 Commercial NM300K-NPs were kindly provided by the Fraunhofer Institute for Molecular Biology and Applied
109 Ecology IME. Each bottle contained 2 g of NM300K diluted in dispersant with a volume of 2 mL. These
110 metallic nanoparticles (NPs) were spherical and not coated and were dispersed in polyoxyethylene glycerol
111 trioleate and polyoxyethylene sorbitan mono-laurate (dispersant) with a nominal silver content of 10.2% by

112 weight. Ninety-nine percent of the particles had a nominal size below 20 nm. Transmission electron microscopy
113 indicated a mean size of 17 ± 8 nm. Smaller NPs of approximately 5 nm were also present (Mendes et al., 2015).

114 AgNO_3 solution was also prepared for comparison with exposure to Ag in ionic form. Silver nitrate salt
115 (AgNO_3) was dissolved in sterile distilled water. The AgNPs and AgNO_3 solution were diluted with ultrapure
116 water to obtain a final Ag concentration of 2 mg mL^{-1} .

117

118 *2.4. Experimental scheme (earthworm exposure)*

119 Earthworms in microcosms (with OECD artificial soil) were exposed to a range of Ag forms and
120 concentrations. Four types of soil mixtures corresponding to 2 controls and 2 exposed conditions were prepared:
121 control (soil only), dispersant (soil spiked with dispersant solution), AgNPs (soil spiked with AgNP solution) and
122 AgNO_3 (soil spiked with AgNO_3 solution) (see Sup. Inf 1). Four different Ag concentrations, C1, C2, C3 and
123 C4, were used for the AgNP and AgNO_3 microcosms: $30 (\pm 20)$, $70 (\pm 10)$, $120 (\pm 15)$ and $280 (\pm 40) \text{ mg kg}^{-1}$
124 (dry matter), respectively (these concentrations were chosen based on mortality rates reported in Garcia-Velasco
125 et al. (2016) and Gomes et al. (2015)). Four different volumes of NM300K dispersant were used in the dispersant
126 microcosms, which served as controls. These volumes were named D1, D2, D3 and D4 and corresponded to the
127 dispersant volumes added in the AgNP microcosms for C1, C2, C3 and C4, respectively. Thus, a total of 13
128 microcosm conditions were established in triplicate. Ten earthworms were introduced in each microcosm, with a
129 total of 390 earthworms. The exposure lasted 4 weeks. No food was added to the initial soil or during exposure.

130

131 *2.5. Analyses*

132 *Life traits.* Survival and biomass were measured. Biomass was followed by comparing the masses of the
133 groups of organisms before and after exposure, and the results were expressed as the percentage loss.

134

135 *Metal concentrations in soils and accumulation in earthworms.* Immediately before exposure (T0),
136 unexposed earthworms from the breeding facility were sacrificed to measure the metal concentrations present in
137 the organisms. After exposure, earthworms were collected from each microcosm and placed in 1% agar for 24
138 hours for depuration (i.e. to remove the gut content). Then, the earthworms were sacrificed by freezing for at
139 least 48 hours and freeze-dried. The organisms were reduced to powder using liquid nitrogen and mineralized by
140 digestion in acid medium (using HNO_3 , H_2SO_4 and HCl_4 in a ratio of 10:2:3) as described by Bernard et al.
141 (2010).

142 Soil samples were collected at the beginning (T₀) and at the end of exposure (T_f = 4 weeks). These samples were
143 freeze-dried and ground with a mortar and a pestle. For mineralization, 300 mg of sample was digested in 7 mL
144 of concentrated HNO₃ using a Berghof microwave digestion system (speed wave MWS-2 microwave pressure
145 digestion). The solutions obtained (mineralized earthworms and soils) were analyzed by ICP-OES (inductively
146 coupled plasma-optical emission spectrometry) (Varian 720-ES, USA). The following classically studied metals
147 were quantified: arsenic (As), chromium (Cr), cadmium (Cd), copper (Cu), nickel (Ni), lead (Pb), zinc (Zn) and
148 Ag.

149

150 *Localization of silver in exposed earthworms using X-ray 3D imaging*

151 Two earthworms were imaged in 3D using X-ray micro-computed tomography (micro-CT): one non-exposed
152 sample and one sample exposed to AgNPs (AgNP-C3) collected after 4 weeks in the dispersant and AgNP
153 microcosms, respectively.

154 *Sample preparation.* After 24 hours of depuration in 1% agar, the earthworms were first anesthetized on ice and
155 fixed for 16 hours in ice-cold 4% paraformaldehyde in 0.1 M phosphate buffer. They were then dehydrated by
156 soaking in a graded series of ethanol solutions (from 30% vol to 100% vol.) and subjected to supercritical point
157 drying (Leica EM CPD300°). In this drying process, ethanol is replaced with liquid CO₂, which avoids the
158 creation of damaging surface tension forces associated with drying by bringing the liquid in the sample to the gas
159 phase without crossing the liquid-gas phase boundary. The dried samples were finally placed in polyimide tubing
160 (Kapton).

161 *3D image acquisition.* 3D imaging of the earthworms was performed with a microXCT-400 X-ray microscope
162 (Zeiss). High-resolution scans were acquired at 40 kV and 250 μA. A total of 2501 projections were collected
163 through 360° rotation with an exposure time of 20 s per projection. A 20x magnification optical objective was
164 selected to achieved an isotropic voxel of 0.9 μm and a field-of-view (FOV) of 0.9x0.9x0.9 mm³. The FOV was
165 centered at the lower end of the earthworm (rings 9 and 10 for the control and exposed earthworms, respectively)
166 and included the coelomic cavity and the nephridia epithelium. The position of the FOV was selected from pre-
167 visualization scans of the entire earthworm with lower spatial resolution (Supporting information 2). Volume
168 reconstruction was performed with XMReconstructed-Parallel Beam-9.0.6445 software using a filtered back
169 projection algorithm.

170 *3D image analysis.* Avizo 8.0 software (Hillsboro, OR, USA) was used for the visualization, processing, and
171 analysis of the reconstructed dataset. The procedure developed in Chaurand et al. (2018) to isolate metal-based

172 NPs was followed. Briefly, images of exposed and non-exposed (control) samples were compared after
173 histogram x-axis normalization (i.e. colormap normalization). The histogram represents the X-ray attenuation in
174 each voxel (expressed as an arbitrary gray scale value, GSV) of the analyzed volume as a function of the number
175 of voxels for each GSV (intensity). The histogram x-axis was normalized using air as an internal standard. After
176 the normalization step, the brilliant voxels in the image of the exposed sample that were not identified in the
177 image of the control sample were attributed to the presence of Ag by thresholding (Supporting information 3).

178
179 *Speciation of silver in soils and earthworms.* Silver speciation in soil and earthworms was determined
180 by X-ray absorption near-edge structure (XANES) spectroscopy, which permits the determination of the local
181 atomic environment (speciation) of targeted atoms present in complex media. Silver K-edge (25.51 keV)
182 XANES spectra were acquired at the European Synchrotron Radiation Facility (ESRF, France) on the FAME
183 beamline (BM30b) with Si(220) monochromator crystals (Proux et al., 2005). Prior to analysis, the earthworm
184 samples were lyophilized, ground and pressed into 5-mm pellets. Spectral acquisition was performed at liquid
185 helium temperature to avoid sample evolution under the beam. Measurements were carried out in fluorescence
186 mode using a 30-element Canberra Ge solid-state detector. Each spectrum was the sum of at least three scans. A
187 set of model compounds including metallic AgNPs, AgNO₃, Ag₂S, AgCl, Ag-thiocarbamate (Ag-thio), and Ag-
188 humic acid (Ag-HA) was run in transmission mode. Normalization data reduction and linear combination fitting
189 (LCF) were performed according to standard methods using Athena software (Ravel and Newville, 2005). The
190 residual factor of LCF was calculated according to the formula $R = \frac{\sum(\text{exp} - \text{fit})^2}{\sum(\text{exp})^2}$, where the sums are
191 over the data points in the fitting region. At each step of the fitting, an additional reference spectrum was added
192 if the following two conditions were true: the R factor decreased by 20% or more and the additional reference
193 had a contribution equal to or higher than 10% among Ag species.

194
195 *2.6. Statistical analysis*

196 For biomass, mortality and metal content in earthworms, the majority of the data did not follow a
197 normal distribution, and the variances were not homogeneous (Shapiro, Liliefors and Bartlett tests). Thus,
198 Sheirer-Ray-Hare non-parametric tests and post-hoc tests based on ranks were used. For data following a normal
199 distribution with homogeneous variances, ANOVA tests and Tuckey post-hoc tests were used. Correlation
200 matrices (based on the Kendall method) were constructed. Tests were performed using the R package (R Core
201 Team, 2018).

202

203 3. RESULTS

204 *Metal quantities in soil.* At the initial time point, the concentrations of As, Cr, Cu, Ni, Pb and Zn were
205 1.08 (standard deviation 0.34), 1.05 (s.d. 0.30), 5.31 (s.d. 1.22), 0.62 (s.d. 0.38), 10.13 (s.d. 2.11) and 5.16 (s.d.
206 0.66) mg kg⁻¹, respectively. The concentration of Cd was below the detection limit. The Ag concentrations in the
207 microcosms are shown in Table 1. As expected, there was no significant difference in Ag doses between the
208 AgNP and AgNO₃ microcosms at each concentration (C1, C2, C3 and C4). Only very low concentrations of Ag
209 were detected in the control and dispersant microcosms. One control microcosm appeared to have been very
210 slightly contaminated by accident, but its Ag concentration remained negligible compared with the exposure
211 conditions.

212 The concentrations of other metals were very low compared with Ag, which suggests that these metals would not
213 hinder the accumulation of Ag by earthworms.

214

215 *Life traits.* A survival rate of 100% was observed in all of the control, dispersant and AgNP microcosms
216 (Fig. 1). In the AgNO₃ microcosms, dose-dependent mortality was observed, with 6.7% mortality at the lowest
217 concentration and 100% mortality at the highest concentration. During the 4 weeks of exposure, the earthworms
218 lost weight in all microcosms, including the controls. Thus, the loss of weight cannot be linked to Ag
219 contamination. Biomass data for earthworms in the AgNO₃-C4 microcosm are absent due to total mortality.

220

221 *Metals bioaccumulation: silver.* At the end of exposure, the Ag content in earthworms varied among the
222 different treatments (Fig. 2). Silver was not detected in organisms in the control microcosms. In the presence of
223 Ag, earthworms accumulated between 2.8 and 9.9 mg kg⁻¹ (average 5 mg kg⁻¹ of dry matter). The accumulation
224 of Ag in the earthworms exposed to Ag was independent of the form of Ag (NPs or ionic) or the Ag dose in the
225 microcosm. Data for earthworms in the AgNO₃-C3 and AgNO₃-C4 microcosms are absent because the
226 insufficient quantity of material available for analysis due to significant mortality.

227

228 *Metals bioaccumulation: other metals.* No significant variations of metal quantities in earthworm bodies
229 were observed for Cd, Cr, Ni, Pb and Zn compared with the corresponding control. A single significant
230 difference in As concentration was observed between the AgNO₃-C2 microcosm and its control (Supporting
231 information 2). The Cu concentration in earthworms was similar in all treatments without Ag (Fig. 3). In the

232 AgNO₃-C2 microcosm (no results were obtained for the AgNO₃-C3 and AgNO₃-C4 microcosms because of
233 earthworm mortality), there was a decrease in the Cu concentration, but this difference was not significant
234 compared with the control. However, in the AgNP microcosms, earthworms accumulated significantly less Cu
235 (approximately two times less) compared with the controls.

236 In summary, Ag was the only metal present in greater concentrations in earthworms exposed to AgNPs
237 conditions than in those under control conditions.

238

239 *Localization of Ag in earthworms:* Brilliant voxels (i.e. voxels exhibiting high X-ray absorption) were
240 observed in the micro-CT volume of exposed earthworms (AgNP-C3, with 109.57 (\pm 8.05) mg kg⁻¹ of AgNPs).
241 Although this imaging technique cannot identify the source of these brilliant voxels, they were not observed in
242 the non-exposed earthworm volume (Dis-D3, in dispersant) and can therefore be attributed to Ag accumulation
243 areas by thresholding (Fig. 4) due to the absence of differences in bioaccumulation for other elements with high
244 densities (metals). Thresholding provides the distribution of these areas of brilliant voxels (colored in red) in the
245 whole scanned volume. Ag accumulation areas/spots were observed around the digestive tract, in the coelomic
246 cavity, in free cells in the coelomic cavity (coelomocytes) and in the nephridial epithelium (Fig. 4).

247

248 *Speciation of silver.* Ag speciation in OECD soil after 4 weeks of incubation depended on the initial
249 form (NPs or ionic). Ag initially spiked as AgNPs remained mainly metallic, but approximately 15% became
250 complexed with natural organic thiols (Fig. 5). Ag initially spiked as AgNO₃ was linked with humic acid (52%)
251 and organic thiols (33%), and approximately 15% was in metallic form. Regardless of the exposure scenario
252 (AgNPs or AgNO₃), the speciation of Ag accumulated in earthworms was similar and consisted of Ag bound to
253 thiols (Fig. 5).

254

255

256 **4. DISCUSSION**

257

258 OECD soil is a simplified matrix for evaluating the effects of medium- and long-term exposure in a soil
259 naturally deprived of many metals and other contaminants. In the present study, the use of OECD soil allowed
260 the effects of added Ag and the underlying mechanisms to be explored under simplified experimental conditions.
261 To prevent the possible ingestion of additional metals, no food was added to the medium. Use of this medium

262 was therefore appropriate for the main objective of our work, which was to locate the sites of Ag accumulation
263 by micro-CT.

264 High AgNP concentrations did not affect the life traits of *E. fetida* earthworms. The weight loss
265 observed in the AgNPs microcosms was similar to that observed under control conditions and was due to a lack
266 of food. OECD soil is poor in organic matter and nutrients, and food was not provided during the experiment. By
267 contrast, dose-dependent toxicity of AgNO₃ resulting in weight loss and mortality was observed. Thus, the
268 toxicity of Ag⁺ was stronger than that of AgNPs, consistent with previous observations of *E. fetida* in both
269 artificial (Diez-Ortiz et al., 2015a; Gomes et al., 2015; Heckmann et al., 2011) and natural soils (Novo et al.,
270 2015). Higher toxicity of ionic Ag compared with AgNPs has been reported for many plants and animal species
271 (Courtois et al., 2019), and there is a consensus that the toxicity of Ag is mainly due to its ionic form. We
272 recognize that the starvation of the earthworms may have interfered with the results presented here. In the
273 presence of optimal food, the effects of the two forms of Ag might be exacerbated or reduced.

274 Despite the differences in toxicity observed between the treatments, in all conditions with Ag (ionic or
275 NPs), the mean bioaccumulation by earthworms in the body was 4 to 5 mg kg⁻¹ (dry matter). Thus, the form of
276 Ag (NPs or ionic) had no influence on the amount of Ag bioaccumulation. In earthworms, metal accumulation is
277 related not only to food intake but also to dermal absorption of dissolved ions (Vijver et al., 2003). Because of
278 the differences in Ag speciation in soil, one might expect Ag linked to organic matter (humic acids) to be
279 metabolized more readily than thiolated Ag. When combined with the dermal absorption of Ag⁺ ions, this
280 increased metabolism could explain the higher toxicity of AgNO₃. However, (Diez-Ortiz et al., 2015b; Garcia-
281 Velasco et al., 2016) showed that Ag is mainly internalized by soil ingestion. Our bioaccumulation results show
282 that Ag can enter the earthworm body. Ag may also pass through the epidermis as dissolved Ag⁺ ions. Unrine et
283 al. (2008) demonstrated that dermal absorption of Au nanoparticles occurs in earthworms. However, as
284 mentioned previously, dermal absorption is not the main route of metal internalization.

285 Contradictory results were reported by Shoults-Wilson et al. (2010) and Bourdineaud et al. (2019), who
286 showed that *E. fetida* in artificial soil accumulated two to fifteen times more silver when exposed to AgNO₃
287 compared with AgNPs. Interestingly, these authors used AgNPs that were two to three times larger (between 50
288 and 60 nm) than the NM-300K AgNPs used in this study, which may have hindered the dermal absorption and
289 metabolism of AgNPs. Supporting this hypothesis, Unrine et al. (2008) showed that the internalization of
290 metallic NPs (Zn and Au) in *E. fetida* decreased with increasing NP size.

291 The Ag concentration in the soil did not influence Ag bioaccumulation by earthworms, which suggests
292 that a very efficient regulation mechanism limits the internal content of Ag even when the environmental
293 concentration is very high. A similar phenomenon (plateau and regulation) was reported by Coutris et al. (2011),
294 who observed rapid Ag excretion from *E. fetida* after the end of exposure.

295 Regardless of the original form of Ag in the microcosms, the bioaccumulated Ag in earthworms was
296 always bound to organic thiols. However, in OECD soil, even after 4 weeks of incubation, Ag speciation differed
297 greatly between the AgNP and AgNO₃ microcosms, indicating biotransformation of Ag by earthworms. Since a
298 regulation/excretion mechanism limits the Ag content in the body, it is likely that earthworms release Ag after
299 biotransformation. Thus, soil organisms like earthworms might change the speciation of Ag in the environment
300 and, consequently, its availability.

301 3D images of entire earthworms obtained by micro-CT showed that Ag (originating from AgNPs) was
302 stored and/or transiting in chloragogenous tissue, coelomocytes and the nephridial epithelium. A similar result
303 was obtained by Diez-Ortiz et al. (2015b) by X-ray chemical analysis (micro-XRF) of the internal distribution in
304 transverse sections: Ag was observed in the gut wall, liver-like chloragogenous tissue and nephridia. These cells
305 and organs are related to immunity and detoxification functions. Chloragogenous tissue covers the outer part of
306 the intestine and is considered to have a liver-like function. For instance, the chloragogenous tissue accumulates
307 wastes produced by digestion and can sequester metals (Lapied et al., 2010; Morgan and Morgan, 1993; Vijver
308 et al., 2004). Moreover, chloragogenous tissue plays a role in earthworm immunity (Fischer, 1993).
309 Coelomocytes are immune cells involved in the elimination of foreign bodies by phagocytosis and encapsulation
310 (Garcia-Velasco et al., 2017), and at least some coelomocytes are derived from chloragocytes (Hamed et al.,
311 2002). Nephridia are organs involved in osmoregulation and excretion (Davidson et al., 2013).

312 In the present study, accumulation of Ag was concomitant with a decrease in Cu accumulation. Cu is an
313 essential metal that is specifically stored by metallothioneins (MTs). MTs, stress proteins that bind essential and
314 non-essential metals through thiolated bonds, participate in the homeostasis of essential metals such as Zn and
315 Cu as well as non-essential metals such as Cd or mercury (Hg) (Demuyne et al., 2006; Vijver et al., 2004).
316 Interestingly, in earthworms, MTs are preferentially but not exclusively localized in the epithelial cells of the
317 intestine, chloragogenous tissue, coelomocytes and nephridia (Morgan et al., 2004). According to the
318 localization of Ag observed by micro-CT, its internal speciation (linked to a thiolated molecule), and competition
319 with Cu, Ag is probably bound by MTs in earthworms. The same hypothesis was proposed by Baccaro et al.
320 (2018), who also observed that bioaccumulated Ag was related to sulfur. Furthermore, in mice, Ag can bind to

321 MT with higher affinity than Cu (Sugawara and Sugawara, 1984). Consequently, Ag probably displaces Cu from
322 MT. Moreover, Hayashi et al. (2013) and Curieses Silvana et al. (2017) observed changes in the expression of
323 genes encoding MTs in *E. fetida* exposed to AgNPs and AgNO₃ (in natural and OECD soil, respectively).
324 Therefore, it seems that MTs have a role in the detoxification mechanisms of Ag. Taken together, these results
325 suggest a pathway for the absorption, detoxification and excretion of Ag.

326 In summary, Ag is probably mainly taken up by ingestion, absorbed by the gut and at least temporarily
327 stored in chloragogenous tissue before detoxification. For excretion, Ag must be transferred from chloragocytes
328 to the nephridia. Two mechanisms can be proposed. First, MT-metal complexes are discharged from the
329 coelomic cavity and then excreted by the nephridia. This mechanism is supported by the work of Nordberg
330 (1989) and Morgan et al. (2004), who described the capacity of MTs linked to metals to enter excretory organs in
331 mammals and earthworms. Second, Ag could be transferred to coelomocytes in the coelomic cavity and stored,
332 inducing the gene encoding MTH (Brulle et al., 2008). Transfer of Ag into coelomocytes can occur via two
333 pathways: transformation of chloragocytes that have stored Ag into free coelomocyte cells or release of metal-
334 bound MT into the coelomic cavity by chloragocytes and subsequent uptake by coelomocytes. In the event of
335 excessive ingestion of Ag that can be not managed conventionally by storage in proteins and excretion, another
336 mechanism might help limit the levels of Ag in the body. For example, Roubalová et al. (2018) showed that
337 when earthworms are confronted by aggression, earthworms can expel coelomic fluid with coelomocytes via the
338 dorsal pores. This mechanism would quickly remove from the body a large amount of metals trapped in the
339 coelomocytes.

340

341 **Legends of table, figures and supplementary information**

342

343 *Table 1: Silver content in the microcosms at the initial time point (mean in mg kg⁻¹ of dry matter). The results*
344 *were obtained by ICP analysis. Standard deviations are in parentheses.*

345 *Figure 1: A. Mean percentage of weight loss of the earthworm groups in the microcosms between the beginning*
346 *and end of the experiment. B. Mean percentage of earthworm survival in the microcosms between the beginning*
347 *and end of the experiment. The concentrations C1, C2, C3 and C4 correspond to mean concentrations of AgNO₃*
348 *and AgNPs of 33 (± 16), 71 (± 8), 117 (± 11) and 277 (± 24) mg kg⁻¹ (dry matter) (the values were not*
349 *significantly different between the two Ag sources). Asterisks (*) indicate statistically important differences*
350 *between the Ag treatment and control. Lowercase letters in green indicate significant differences in biomass*
351 *between the 4 doses of Ag (for one form of Ag). Lowercase letters in blue indicate significant differences in*
352 *survival between the 4 doses of Ag (for one form of Ag). Uppercase letters in yellow indicate significant*
353 *differences in biomass between the two forms of Ag (NPs or ionic), taking into account all concentrations. 'NA'*
354 *indicates that biomass data were not available due to total mortality.*

355 *Figure 2: Ag content in earthworm bodies (mg kg⁻¹). "AgNPs" corresponds to microcosms with silver*
356 *nanoparticles. "AgNO₃" corresponds to microcosms with silver nitrate. The concentrations C1, C2, C3 and C4*
357 *correspond to 33 (± 16), 71 (± 8), 117 (± 11) and 277 (± 24) mg kg⁻¹ (dry matter) (the mean concentrations of*
358 *AgNO₃ and AgNPs were not significantly different). Stars (*) indicate significant differences from the associated*
359 *control without silver. Lowercase letters in orange indicate significant differences in metal content between the 4*
360 *concentrations (C1, C2, C3 and C4) of Ag (AgNPs and AgNO₃ were not compared). Uppercase letters in yellow*
361 *indicate significant differences in Ag content between the 2 forms of Ag (NPs or ionic), taking into account all*
362 *concentrations. 'NA' indicates that data were not available due to significant mortality.*

363 *Figure 3: Cu contents in earthworm bodies (mg kg⁻¹). "AgNPs" corresponds to microcosms with silver*
364 *nanoparticles. "AgNO₃" corresponds to microcosms with silver nitrate. The concentrations C1, C2, C3 and C4*
365 *correspond to 33 (± 16), 71 (± 8), 117 (± 11) and 277 (± 24) mg kg⁻¹ (dry matter) (mean concentrations of*
366 *AgNO₃ and AgNPs, which were not significantly different). Stars (*) indicate significant differences from the*
367 *associated control without Ag. Lowercase letters in purple indicate significant differences in metal contents*
368 *among the 4 doses of Ag (for one form of Ag). Uppercase letters in yellow indicate significant differences in Cu*
369 *content between the 2 forms of Ag (NPs or ionic), taking into account all concentrations. Lowercase letters in*

370 black indicate significant differences in Cu content between the 2 forms of Ag at one given concentration. 'NA'
371 indicates that data were not available due to significant mortality.

372 Figure 4: Examples of 2D orthoslices extracted from the reconstructed volume of (A) non-exposed earthworms
373 (Dis-D3) and (B, C, D) exposed earthworms (AgNP-C3). The digestive tract (d), free cells in the coelomic cavity
374 (coelomocytes) (c) and the nephridial epithelium (n) are indicated. The pixels colored in red in (B, C, D) in
375 dotted circles are brilliant voxels isolated by thresholding and associated with Ag. These brilliant pixels are not
376 observed in (A). 1 px = 0.9 μm .

377 Figure 5: A. Linear combination fitting (LCF) of the XANES spectra of the samples collected at different time
378 points (dotted lines) and experimental spectra (solid lines) of soil and earthworms after 4 weeks of exposure to
379 AgNPs and AgNO₃. The curves for the samples are colored as follows: dark green, soil spiked with AgNO₃; dark
380 blue, soil spiked with AgNPs; light green, earthworms exposed to AgNO₃; light blue, earthworms exposed to
381 AgNPs. B. XANES spectra of the model compounds used for LCF. Ag-HA (in yellow) was used as a proxy for Ag
382 complexed to natural organic matter (humic acids). AgNPs (in grey) corresponds to the initial NM300K AgNPs
383 used for the experiment. Ag-thiol (in purple) was used as a proxy for Ag bound to an organic thiol. Ag₂S (in
384 orange) corresponds to silver sulfide (acanthite mineral).

385 Sup. Inf. 1: Scheme of the experimental design. "Control" corresponds to the microcosm without any inputs.
386 "AgNPs" corresponds to silver nanoparticles. "Dis" corresponds to dispersant. "AgNO₃" corresponds to silver
387 nitrate. The concentrations C1, C2, C3 and C4 correspond to 33 (\pm 16), 71 (\pm 8), 117 (\pm 11) and 277 (\pm 24) mg
388 kg⁻¹ of Ag (dry matter) (the mean concentrations of AgNO₃ and AgNPs were not significantly different). The
389 volumes D1, D2, D3 and D4 correspond to the volumes of dispersant added to the microcosms. Dispersant was
390 added in the same amount as in the corresponding AgNPs microcosms, that is, 1.599, 2.666, 5.331 and 10.662
391 mL.

392 *Sup. Inf. 2: Metal contents in earthworms (mean in mg kg⁻¹). The results were obtained by ICP analysis.*
 393 *“Control” corresponds to the microcosm without silver addition. “AgNPs” corresponds to silver nanoparticles.*
 394 *“Dis” corresponds to dispersant. “AgNO₃” corresponds to silver nitrate. The concentrations C1, C2, C3 and C4*
 395 *correspond to 33 (± 20), 71 (± 10), 117 (± 15) and 277 (± 45) mg kg⁻¹ (dry matter) (the mean concentrations of*
 396 *AgNO₃ and AgNPs were not significantly different). Stars (*) indicate significant differences between the*
 397 *condition with Ag and the associated control without Ag. Standard deviations are in parentheses.*

398 *Sup. Inf. 3: 3D imaging of an earthworm by micro-CT. (top) Selection of FOV for high-resolution micro-CT*
 399 *scan. (bottom) 3D image analysis procedure for isolating Ag accumulation areas (normalization and*
 400 *thresholding step).*

Concentration	Control microcosms	Dispersant	AgNPs	AgNO ₃
C1 (or D1)	1.95 (1.23)	0.69 (0.97)	26.33 (10.63)	39.53 (20.66)
C2 (or D2)		0.61 (1.06)	70.50 (8.15)	71.03 (8.71)
C3 (or D3)		0.18 (0.31)	109.57 (8.05)	124.30 (7.59)
C4 (or D4)		0.00 (0.00)	262.93 (27.87)	290.90 (10.81)
