15 **Abstract:**

16 The ecological transition zones also known as ecotones are specific ecosystems but how global change
17 will affect their biodiversity and functioning is poorly understood. In the case of the areas at the
18 interface between riparian forest and salt meadows the biodiversity conservation remains a major
19 issue. The aim of this work was to evaluate the effects of a salty environment on *Fraxinus angustifolia*
20 a non-halophyte species. For this, the photochemistry of PSII was *in situ* explored during the summer
21 between 2007 and 2016. The predawn maximum quantum efficiency of PSII (Fv/Fm) was always
22 greater than 0.8 which indicates an absence of chronic photoinhibition induced by salinity. During
23 these years, the light kinetic of the actual quantum yield of PSII (Φ_{PSII}) was studied. It appears that
24 this yield is generally higher in salty environments than in the riparian forest. Multivariate analysis,
25 showed that the dissipation regulated light energy fraction (Φ_{NPQ}), the photochemical quenching (qP)
26 and the Fd/Fs ratio constitute the main explanatory variables of Φ_{PSII} changes. The subsequent two-
27 way-ANCOVA carried out demonstrated that Φ_{NPQ} was weaker in saline environments, suggesting a
28 better efficiency of photosystem collecting antennas. Meanwhile, the analysis of photosynthetic
29 pigments did not exhibited a salt effect except the significant accumulation of chlorophyll a in 2016.
30 In order to address the question of the salt-related toxicity, sodium ion contents in the leaves were
31 found to be identical in the two sites, suggesting the establishment of an energy-dependent mechanism
32 of salt exclusion/retention in roots. The growth rings of *F.angustifolia* in saline areas highly follows
33 the annual water deficit changes. Between 2007 and 2016, the biomass in the salt meadow was higher
34 with a peak in 2011 representing 60% of the biomass of control individuals. But, since 2011 a

35 continuous decline of growth was recorded. Water conditions seem to constitute a limiting factor even
36 if the photosynthetic apparatus generates the excess metabolic energy necessary to cope with the saline
37 toxicity. This study thus highlighted the plasticity of the photochemistry of the PSII depending to the
38 environmental conditions of the salt meadows. It also shows the vulnerability of an ecotone through
39 the decline in the productivity of a glycophyte with climate change. This augurs for changes in the
40 composition of plant communities which is in favor of strict halophytes.

41 **Key words:** *Fraxinus angustifolia*; salt stress; PSII photochemistry; salt meadow; water
42 deficit; ecophysiology.

43

44 1. Introduction

45 Global change projections of wetland ecosystems such as salt marshes include sea-level rise
46 and extreme climatic events (Thorne et al., 2012). Salt meadows spread over narrow
47 transitional areas between sea and terrestrial environments which are considered as high-risk
48 zones subject to climate change impacts (Thorne et al., 2012). In these ecosystems, several
49 taxonomic groups of plants coexist with salt requirements which are highly contrasted. They
50 are divided into euhalophytes and facultative halophytes but typically an halophyte is defined
51 as a plant that grows in soil conditions of more than 200 mM NaCl concentration (Flowers
52 and Colmer, 2008) . Besides salinity conditions, biotic factors such as competition between
53 individuals are also to be considered in terms of saltmarshes functioning (Pennings et al.,
54 2005). Overall, it appears that the hydro-period regime that depends on specific precipitation
55 and evaporation conditions is one of the main factors regulating the creation of niches for
56 wetland plant species (Foti et al., 2012).

57 The question of the spatial distribution of species between the seashore and the boundary of
58 non-halophytic terrestrial vegetation has been addressed by several authors (Pennings et al.,
59 2005; Silvestri et al., 2005). For instance taking into account the elevation gradient, four
60 clusters reflecting the composition of plant community were shown (Bang et al., 2018).
61 However, the scarcity of studies focussing on the salt marsh-terrestrial boundaries was
62 underlined (Traut, 2005; Veldkornet et al., 2015). Indeed, the border between the salt marsh
63 and the adjacent upland (terrestrial vegetation) occupies a narrow surface also recognized as
64 ecotone. These habitats are submitted to particular abiotic conditions leading to a plant
65 community assembly that is specific to one or both of the adjacent ecosystems. In the
66 Mediterranean region and in the Bouches-du-Rhône in particular, salt meadows develop at the

67 confluence of rivers and the Etang de Berre. This is the case for the river Arc which exhibits a
68 steep fall of the presence of trees from the riparian forest in the upland. Among the riparian
69 woody species only few specimens of *Fraxinus angustifolia* Vahl (narrow-leaved ash) were
70 observed in the salt marsh upland transition zone possibly in the area so-called ecotone.
71 Hence, information on species with narrow biotope tolerance might best characterize the
72 effects of climate change (James and Zedler, 2000).

73
74 *F. angustifolia* belongs to the family Oleaceae and is widespread across Southern Europe. In
75 Mediterranean basin the plant is often encountered in riparian corridors. In Croatia for
76 example, narrow-leaved ash is considered as one of the most important tree species of
77 lowland floodplain forests and its sensitivity to drought was shown (Drvodelic et al., 2016).
78 But, how *F. angustifolia* will cope with salinity and drought expected with climate change is
79 poorly explored. More generally exploring the mechanisms of glycophytes adaptation to
80 salinity is becoming a great challenge because soil salinization is recognized as a global
81 problem resulting in soil degradation, arable land surface decrease and ecological
82 environmental disturbance (Hu et al., 2019). By comparing two *Solanum* species, one
83 glycophyte and the other salt-tolerant, it has been shown that ethylene induction plays a key
84 role in salinity tolerance through an improved stomatal conductance, an efficient osmotic
85 adjustment and the increase of Na⁺ accumulation in shoots (Gharbi et al., 2017). In roots of
86 the glycophyte *Arabidopsis thaliana* (L.) Heynh., salt stress triggered principally defence
87 proteins as those involved in ROS scavenging whereas for the xero-halophyte *Zygophyllum*
88 *xanthoxylum* Engl. Ex Dippel, Na⁺ uptake was improved in addition with metabolic shifts
89 towards *de novo* synthesis of glucose in order to sustain growth (Chai et al., 2019). Similarly,
90 retention of sodium cations in roots thus preventing their translocation to shoots is considered
91 as a key adaptive mechanism of glycophytes to salt stress (Assaha et al., 2017; Hasegawa,
92 2013). Root sequestration of sodium cations not only improves the water balance by adequate
93 osmotic adjustment but also preserves the photosynthetic machinery from ionic toxicity. Thus,
94 from the xero-halophyte *Nitraria retusa* (Forssk.) Asch., PSII photochemistry and carotenoid
95 content were not affected by salinity whereas a significant reduction in pigment
96 concentrations and chlorophyll fluorescence parameters were observed from the glycophyte
97 *Medicago arborea* L. (Boughalleb et al., 2009). This led to suggest that the decrease of the
98 photosynthetic activity is likely the result of damages in the photosynthetic apparatus rather
99 than factors driving stomatal closure. Other authors have also shown that the maximum
100 quantum efficiency of PSII is highly reduced for rice salt-sensitive cultivars consecutively to

101 salt stress application as compared to salt-tolerant cultivars. Similarly, the minimum
102 fluorescence intensity (F₀), the actual quantum efficiency (PSII) and the Non-Photochemical
103 Quenching (NPQ) were identified as the main fluorescence parameters that change depending
104 on the intensity of salt stress (Tsai et al., 2019). Besides the ionic toxicity induced by soil
105 salinity, water availability also constitutes a major constraint for glycophytes survival in
106 saltmarshes. Although, chlorophyll a fluorescence has been used as a signal for monitoring
107 plants response to drought in several reports (Dalberto et al., 2017; Vaz et al., 2016; Wang et
108 al., 2016) few works deal with both drought and salinity effects. Moreover, plant *in situ* often
109 experience multifactorial stress conditions.

110 Understanding how a glycophyte may stabilize its photosynthesis activity also maintaining its
111 ionic homeostasis under high soil salinity can help provide insight in terms of plant breeding
112 and ecological management. In this report we evaluate the ecological fitness of a glycophyte
113 *F. angustifolia* native to the saltmarsh/upland transition zone also termed ecotone upon a
114 highly sensitive to global climatic change variables. Second, we hypothesized that the
115 predicted increase warming and summer drought in Mediterranean basin would lead to more
116 NaCl accumulation requiring additional metabolic energy to sustain growth and defence
117 molecules biosynthesis. Finally we considered that the global change would drive profound
118 changes in the assemblages of plant communities into the ecotones of the deltaic zones of the
119 Mediterranean rivers.

120 2. Material and methods

121 2.1 The study site

122 The area that was the subject of this study is located in the Arc delta ecotone and in the
123 riparian forest of the same river (Berre-l'Etang, France). The Arc delta occupies an area of
124 190 ha. It is associated with hydromorphic soils covered with a halophilic vegetation, which
125 extend about 700 m wide. Upstream the deltaic zone (1.4 km), the riparian forest is mainly
126 constituted by ash, poplar and white willow. The ecotone was characterized by the occurrence
127 of both euhalophytes and facultative halophytes as well as some specimens of *Fraxinus*
128 *angustifolia*, namely: *Sueda vera* Forssk. ex J.F.Gmel., *Limonium narbonense* Mill.,
129 *Limonium cuspidatum* (Delort) Erben, *Chenopodium chenopodioides* (L.) Aellen, *Tamarix*
130 *gallica* L., *Obione portulacoides* (=Atriplex portulacoides L.) and *Plantago coronopus* L. The
131 meteorological data were obtained from the nearest station namely Marignane which is

132 located at about 11 km away as the crow flies. Five to six trees (*F. angustifolia*) of similar
133 height and diameter were chosen in each zone during this study.

134 2.2 Modulated chlorophyll fluorescence parameters monitoring

135 Fluorescence data were obtained using Hansatech fluorometer (FMS2). Leaves (3 per tree)
136 were dark-adapted for 30 min using the dark-adaptation clip prior to the application of a low
137 pulsed amber light intensity to determine the minimum fluorescence (F_0) followed by the
138 application of a saturating pulse for the maximum fluorescence measurement (F_m) such that
139 all primary quinone electron acceptors in PSII are closed (Q_A fully reduced). These data allow
140 to calculate the maximum quantum efficiency through the ratio F_v/F_m where F_v ($F_m - F_0$)
141 corresponds to the variable fluorescence. This ratio was determined at predawn, dawn and in
142 diurnal period.

143 The diurnal course of chlorophyll parameters was monitored on 28th august 2007 from 9:00 h
144 to 18:00 h by using successively the dark adaptation clip and the PAR/temperature leaf-clip
145 which is designed for measurements under ambient light conditions. Thus additional variables
146 were recorded from light acclimated leaves: minimum (F'_0) maximum (F'_m) and the steady
147 state (F_s) values of fluorescence. Through these data as well as F_m and F_0 the following
148 fluorescence parameters were determined: The photochemical efficiency in the light adapted
149 state of photosystem II (Φ_{PSII}) calculated as $(F'_m - F_s)/F'_m$ according to Genty et al. (1989), the
150 non-photochemical quenching coefficient of chlorophyll fluorescence (NPQ), calculated as
151 $(F_m - F'_m)/F'_m$ (Bilger and Björkman, 1990) which expresses the dissipation of excess energy
152 as heat and the photochemical quenching (qP) coefficient, which was calculated from $(F'_m -$
153 $F_s)/(F'_m - F'_0)$ that gives an indication of the proportion of PSII reaction centers that are open
154 (Maxwell and Johnson, 2000). An alternative non-photochemical quenching coefficient, QNP
155 $= (F_m - F'_m)/(F_m - F_0)$ was also determined (Schreiber et al., 1986).

156 Light response kinetic measurements were carried out at dawn by selecting four incident
157 photosynthetically active irradiance (PAR) intensities in order to simulate the half diurnal
158 light radiation change: 300, 600, 900 and 1200 $\mu\text{mol Photons m}^{-2}\text{s}^{-1}$. The light saturating pulse
159 ($8.000 \mu\text{mol Photons m}^{-2}\text{s}^{-1}$) was applied for each PAR intensity only when the steady-state
160 fluorescence intensity (F_s) was reached. This was checked prior to the design of a specific
161 light kinetic script. In addition to the above-mentioned fluorescence parameters, other
162 parameters were calculated for each actinic light application: the quantum efficiency of
163 regulated ΔpH and/or xanthophyll-dependent non-photochemical dissipation processes in the

164 antenna of PSII ($\Phi_{NPQ} = F_s/F'_m - F_s/F_m$). The quantum efficiency of the constitutive non-
165 photochemical fluorescence and energy dissipation ($\Phi_{f,D} = F_s/F_m$) according to Hendrickson et
166 al. (2005). The Chlorophyll fluorescence decrease ratio was calculated as: $F_d/F_s = F_m - F_s/F_s$
167 (Lichtenthaler et al., 2005). Also, the rate of the linear electron transport was determined:

168 $ETR = 0.5 \times PAR \times 0.87 \times \Phi_{PSII}$ assuming that the photon flux are equally distributed between
169 the two photosystems.

170 *2.3 Simultaneous gas exchange and fluorescence monitoring*

171 The leaf gas exchange and fluorescence parameters were simultaneously determined using a
172 gas exchange system (LI-6400XT; LI-COR Inc., Lincoln, NE, USA) equipped with a
173 fluorescence chamber head. CO_2 assimilation rate (A), internal CO_2 (C_i) and stomatal
174 conductance (g_s) were determined. All the measurements were carried out at $25^\circ C$ and the
175 relative humidity of the chamber was set at 70%, while the amount of blue light was set to
176 10% of the photosynthetic photon flux density for optimized stomatal aperture. In light-
177 adapted leaves, the steady state fluorescence yield (F_s) was recorded and the maximum
178 fluorescence (F'_m) obtained after application of a saturating white light pulse ($8.000 \mu mol$
179 $photons\ m^{-2}\ s^{-1}$, 0.8 s). The actinic light was then turned off and far-red illumination was
180 applied ($2 \mu mol\ photons\ m^{-2}\ s^{-1}$) to measure the light-adapted minimum fluorescence (F'_0).
181 Using these parameters, Φ_{PSII} , qP and the ratio $F'_v/F'_m = (F'_m - F'_0)/F'_m$ which corresponds
182 to the efficiency of the energy harvesting by the oxidized PSII reaction centers in light
183 condition were determined.

184

185 *2.4 Predawn leaf water potential determination*

186 Water potential (Ψ) was measured using a pressure chamber of Scholander type (Scholander
187 et al., 1965), from mature fully expanded leaves of randomly selected plants. The
188 measurements were carried out from five trees per site at 05:00 h then finished before sunrise.

189 *2.5 Soil and leaf sodium ions concentration*

190 Five trees and five soil samples were considered for each condition: salt meadow and the
191 control. Plant samples was composed by a pool of five leaves per tree. Soil and leaf samples
192 were ash transformed in a muffle furnace. The extracted solutions were analysed for Na^+
193 concentrations by using an Ion Chromatograph (Dionex Model DX 120, USA). The column

194 used was a CS16 with hydroxymethanesulfonic acid (26 mM) as eluent which a flow rate set
195 at 1ml/min. Electrical conductivity was the mode of cations detection.

196

197

198 *2.6 Photosynthetic pigments analysis*

199 Leaves (a pool of five leaves per tree from five trees in each site) were collected at predawn
200 then wrapped in aluminum foil to avoid for degradation of pigments by light and finally
201 stored at -20°C until analysis in the laboratory. Chlorophylls and total carotenoids were
202 extracted with acetone (80%) and filtered through Millipore membrane (0.2 μm pore size).
203 Quantification was performed with a spectrophotometer (BioMateTM3) by measuring their
204 absorbance at 663, 646 and 470 nm (Lichtenthaler and Wellburn, 1983).

205 *2.7 Dendrochronology*

206 The sampling process took place during the spring 2017. We selected six dominant and
207 mature ashes separated by at least 8 m from each other in the salt meadow; six other dominant
208 ashes were selected as control trees. One core per tree at 1.3 m height was collected with a
209 Swedish increment borer. In the laboratory, cores were prepared according to standard
210 dendrochronological procedures (Fritts 1976). All cores were air-dried, glued onto groove
211 boards, sanded with progressively finer grade sandpaper to produce smoothed surfaces on
212 which the tree-ring boundaries were clearly visible and visually crossdated under a binocular
213 to ensure that each ring was dated to the correct calendar year. Then, ring-width series were
214 measured to the nearest 1/100 mm using a LINTAB6 measuring table (Rinntech®) and the
215 TSAP-Win software (Rinn 2003). All ring-width series were crossdated graphically and
216 crossdating was checked using the COFECHA software (Holmes, 1983) by assessing the
217 consistency of the different ring-width series among trees.

218

219 *2.8 Statistical analysis*

220 A Student test was performed to compare the two sites for each interval of time regarding to
221 the diurnal measurements of fluorescence parameters.

222 For the predawn physiological indicators (F_v/F_m , pigment content and Ψ) a two-way ANOVA
223 was designed to assess the relationship between the two independent variables (Site x Year)
224 on each dependent variable followed by Tukey's HSD (Honestly Significant Differences)

225 tests. The PSII photochemistry parameters obtained from light kinetics were first treated by a
226 multivariate analysis in order to determine the main explicative fluorescence parameters of
227 the actual quantum yield kinetics. This was performed using R statistical software (R
228 development Core Team, 2009) and the package “FactoMineR” Thus, covariance analyses
229 (ANCOVA), with light intensities fixed as covariate were used to examine the effect of site
230 and year on the pertinent explicative fluorescence variables. Curves fitting and statistical
231 analyses were performed using Statgraphics Centurion XV software and R statistical
232 software.

233

234 3. Results

235 3.1 Annual changes in climatic conditions of the study site

236 The study area was located near the village of Mauran at 11 km of the nearest meteorological
237 station which is that of Marignane (France). As shown in table 1, during this last decade,
238 summer air temperature varied from 23 to 25°C. There was no significant difference between
239 the years (one-way-ANOVA, $F=2.12$, $P=0.065$). However, the cumulated precipitation varied
240 considerably (10-139 mm) resulting in similar changes in soil water deficit. For instance the
241 highest water deficit was recorded in 2016 (-659 mm) while the lowest one was observed in
242 2011 (-4.18 mm).

243 3.2 Interannual radial growth

244 Analyzes of the cores collected from the individuals located at the two study sites allowed us
245 to address their radial growth over the last ten years. The results clearly show that *F.*
246 *angustifolia* grows better in salt meadows than the control site (Fig. 1). A peak of radial
247 growth was recorded in 2014, where growth in the saline area was twice that of the riparian
248 bank. However, since 2011, this growth has been falling to equal the radial growth of
249 individuals in the control habitat.

250 3.3 Leaf water and sodium ion status

251 *F. angustifolia* environmental conditions in both salt meadow and riparian forest bank were
252 first characterized at the beginning of august 2007. Soil water availability was characterized
253 by the measurement of leaf water potential in the absence of any transpiration flux as well as
254 leaves and soil sodium chloride contents. Predawn water potential was higher in control stand

255 compared to salt marsh individuals. Leaves Na^+ content were similar while soil Na^+ content in
256 salt meadow site was about 13-fold that of the riparian forest bank (Table 2).

257

258

259 *3.4 The diurnal variation of chlorophyll fluorescence parameters*

260 From 9:00 h to 18:00 h several chlorophyll fluorescence data were recorded (Fig. 2). The
261 maximum quantum efficiency of PSII (F_v/F_m) was significantly higher for samples of salt
262 meadow site compared to those of the riparian forest only from 9:00 h to 13:00 h. For
263 instance, at 13:00 h the ratios F_v/F_m were 0.739 and 0.614, respectively (Fig. 2A). When
264 leaves were light acclimated, the actual efficiency of PSII photochemistry (Φ_{PSII}) decreases by
265 late morning to 16:00 h then rises until 6:00 h pm in both cases (Fig. 2B). However at 9:00h
266 Φ_{PSII} of *F. angustifolia* located in salty soils was about 2-fold that of none salty grown
267 specimens. The exitonic energy used for the reduction of the plastoquinone pool, determined
268 by the photochemical quenching coefficient (qP) exhibited similar patterns for both sites but
269 with a significant difference obtained also only at 9:00 h am (Fig. 2C). Alternatively, the
270 excess of absorbed excitation energy may be dissipated through non-photochemical
271 processes referred as NPQ. No significant difference was found between the two sites in the
272 morning (Fig. 2D).

273 Hence, it seems that *F. angustifolia* quantum yield in salty soil condition is higher than the
274 control during the morning and this may be explained by both photochemical quenching
275 mechanisms and PSII antenna efficiency. This led to further investigation regarding to the
276 predawn maximum quantum efficiency and the plant response to light kinetic taking into
277 account the interannual variability.

278 *3.5 Predawn F_v/F_m and steady-state light response of chlorophyll fluorescence parameters in* 279 *field conditions*

280 *3.5.1 Predawn F_v/F_m*

281 The analysis of the maximum quantum efficiency carried out between 2007 and 2016 showed
282 that the factors site and year interact together ($F=5.31$; $p<0.001$). Hence, the predawn ratios
283 F_v/F_m of the sites were compared year by year. As a result (Fig. 3) *F. angustifolia* exhibited
284 significant differences between sites in 2009 and 2016. For the former date, a lower ratio was
285 obtained in salt meadow compare to the control; 0.819 and 0.886, respectively. For the latter,

286 an opposite response was shown because salt meadow Fv/Fm was about 0.05 units higher
287 than the data recorded from control samples. The predawn ratio was also tested site by site for
288 all the years which revealed that the ratio Fv/Fm tends to be lower in control with greater
289 variability throughout the years (Fig. 4).

290

291 3.5.2 Dawn light kinetic fluorescence parameters measurements

292 Solar course during half a day was mimed by the implementation of a script where the
293 intensity of the light increases from 300 to 1200 $\mu\text{mol. photon.m}^{-2}.\text{s}^{-1}$ in 4 steps. Fluorescence
294 data were recorded during 6 years then first examined through the quantum yield kinetic.
295 Two-way ANCOVA with light intensity as covariate was carried out. A significant effect of
296 the factors year ($F=61.54$ $p<0.001$) and site ($F=9.38$ $p<0.001$) was shown and no interaction
297 was found between them. Thus, the site effect on the dependent variable Φ_{PSII} was tested year
298 by year. As a result, the photochemical quantum yield decreases exponentially with light
299 intensity (Fig. 5) with significant differences between the two sites except in 2014. The
300 photosynthetic performance of individuals in salt meadows was higher than that of the
301 controls. It is thus possible to summarize the functioning of the photosynthetic machinery in 2
302 types of response. The first one is characterized by large variations in the actual quantum
303 yield at low light intensities as in 2007, 2008 and 2016. The second type of response is
304 manifested by an increasing difference as light intensities increase. This is the case in 2015
305 and 2009 where the quantum yields were about 0.8. It appears that soil salinity contributes to
306 increase *F. angustifolia* PSII quantum yield through physiological mechanisms that change
307 depending to the year. This arises the question of the identification of the fluorescence
308 parameters that explain these variations of the effective quantum yield. A multivariate
309 analysis was performed in order to prioritize the fluorescence parameters involved. The factor
310 map of the variables denotes a total variance of 89.46 % (Fig.6). Interestingly, Φ_{PSII} is
311 strongly correlated to axis 1 (correlation coefficient: 0.99) followed by Φ_{NPQ} (correlation
312 coefficient: 0.96) and qP (correlation coefficient: -0.87). As for axis 2, the main explanatory
313 variable is Fd/Fs (correlation coefficient: 0.87). In summary the variations of Φ_{PSII} are mainly
314 explained by non-photochemical quenching mechanisms followed by the ratio Fd/Fs. For the
315 former, the two-way ANCOVA performed showed a significant site ($F=11.69$, $p<0.001$) and
316 year ($F=50.35$, $p<0.001$) effects, no interaction was found between the two factors. In these
317 conditions, Φ_{NPQ} was compared between sites, year by year. The results showed that Φ_{NPQ} in
318 the salty areas was lower than that of the control except in 2014, 2015 (Fig. 7).

319

320 *3.6 Gas exchange and fluorescence measurements*

321 Simultaneous measurements of gas exchanges and fluorescence data were carried out in 2009
322 with a Licor 6400 equipped with the fluorescence chamber. The responses of *F. angustifolia*
323 to salt meadow environmental conditions were examined through the measurements of leaf
324 net photosynthesis (A), leaf internal CO₂ concentration (Ci), PSII antenna efficiency
325 (Fv'/Fm'), the photochemical quenching qP and the quantum yield of PSII. As shown in table
326 3 salt meadow plants exhibited a slight increase of the net photosynthesis (3.17 μmol. CO₂.m⁻².s⁻¹)
327 compared to the controls (2.93 μmol. CO₂.m⁻².s⁻¹). Similar result was also obtained for
328 leaf internal CO₂ content. However, no differences were found for the quantum yield and
329 related fluorescence data.

330

331 *3.7 Photosynthetic pigments analysis*

332 The concentrations of chlorophylls and total carotenoids contents were measured from the
333 two sites throughout six years. Based on the data obtained for chlorophyll a there was an
334 interaction between the factors site and year (F=2.43; p<0.05). Sites were thus compared year
335 by year but no significant difference was found except in 2016 where chlorophyll a contents
336 from salt meadow samples were 3-fold higher compare to the controls (Fig. 8A). For the other
337 pigments no interaction was ascertained between the two factors and significant changes were
338 obtained only over the years. Hence, the highest contents of chlorophyll b were recorded in
339 2008 whereas the lowest values were obtained in 2007 (Fig. 8B). Total carotenoids
340 concentration (Fig. 8C) in 2008 was about 75 μg/g of DW which represents the highest values
341 recorded during the years investigated while the lowest data were obtained in 2015 (27 μg/g
342 of DW).

343

344 **4. Discussion**

345 In this report we showed for the first time a long term survey of the *in situ* adaptation of a
346 glycophyte to salt march conditions based on chlorophyll fluorescence signals. The model
347 used was *F. angustifolia* which occurs naturally in several Mediterranean deltaic zones unlike
348 to most of riparian forest species.

349 During the last decade, the tree-rings of individuals growing in the salt marsh showed clearly
350 two effects: on one hand, the biomass is greater than that of the individuals in the control area
351 (Fig. 1) and on the other hand, this biomass varies according to the fluctuations of water
352 deficit (Table 1). In particular, from the peak of 2011 the biomass has steadily decreased to
353 reach that of the control individuals in 2017. A higher biomass could be the result of intense
354 photosynthetic activity at the level of both light and enzymatic reactions but also the fact of a
355 greater availability of nutrients. Indeed, river mouths are recognized as areas with high
356 concentrations of mineral elements because of the importance of alluvial deposits. This is true
357 for halophytes but glycophytes have to cope with salinity: 13-fold higher as found in this
358 study (Table 2) suggesting the need of additional metabolic energy. Thus, the light-dependent
359 reactions of photosynthesis were followed through several parameters based on the
360 fluorescence of chlorophyll a. Measurements of the maximum quantum efficiency before
361 sunrise did not show any particular stress since the values obtained were all greater than 0.75
362 (Björkman and Demmig, 1987). This also indicates the lack of chronic photoinhibition or salt
363 induced toxicity to PSII (Yan et al., 2015). However, for the year 2016, which was
364 characterized by the greatest water deficit ($P=10$ mm), the ratio F_v/F_m measured in the saline
365 zone was significantly higher than of the control zone. Similarly, the levels of chlorophyll a
366 were three times higher compared to individuals in the control zone (Fig.7A). This is an
367 unexpected result because the ratio F_v/F_m trends to decrease with stress intensity as well as
368 chlorophyll a contents (Manaa et al., 2019; Masondo et al., 2019). Nevertheless, the increase
369 of chlorophyll a content under salinity was observed from individuals of *Phragmites karka*
370 (Retz.) Trin ex Sternd (Shoukat et al., 2019) as such, the increase of chlorophyll content has
371 been considered to be a marker of resistance to salinity (Acosta-Motos et al., 2017). This
372 would mean that the increase in the F_v/F_m ratio corresponds to an adaptive response of *F.*
373 *angustifolia* to both drought and salinity. Indeed chlorophyll a is present as a dimer in the
374 reaction center of the photosystems, an increase in its concentration could result in an increase
375 in the number of photosystems and consequently a better photosynthetic capacity of
376 individuals to mitigate the environmental constraints.

377 Given the absence of chronic photoinhibition, fluorescence measurements were conducted in
378 order to understand the dynamics of photosynthesis light reactions. Initially, the
379 measurements made between 9:00 h and 18:00 h clearly showed that the actual photochemical
380 yield (Φ_{PSII}) of individuals in salty environment was higher than those in the control area (Fig.
381 2B). Subsequently, kinetics measurements were carried out by simulation of light intensity
382 variations for half a day. During the six years of measurement the kinetic curves show that

383 Φ_{PSII} in saline medium is always higher than the control except during 2014. The water
384 conditions alone do not explain this difference between the years because the water deficits
385 between the years 2014 and 2015 were roughly the same (138 and 139). It seems that other
386 environmental factors contributed to buffer Φ_{PSII} variations in 2014. Nevertheless, the
387 adaptive capacity of an invasive plant in salt-meadows, *Spartina patens* (Aiton) Muhl. was
388 related to maintaining a high level of Φ_{PSII} despite the increase in salinity (Duarte et al.,
389 2015). We can therefore consider that maintaining a high level of Φ_{PSII} of *F. angustifolia* in a
390 salty environment is an adaptive trait.

391

392 In order to highlight the mechanisms involved in the regulation of Φ_{PSII} , a multivariate
393 analysis was conducted. PCA analysis revealed that the main explanatory variables were the
394 fraction of absorbed energy that is dissipated thermally by the ΔpH - and the xanthophyll
395 cycle-dependent quenching in PSII (Φ_{NPQ}), qP and Fd/Fs ratio. The one-way ANCOVA
396 performed on Φ_{NPQ} confirms significant differences between salty and control environments
397 (Fig. 6) with the exception of the years 2014 and 2015. In particular, the high yields of Φ_{PSII}
398 in saline environments may be explained by a better efficiency in the conversion of the light
399 energy absorbed into reducing power since Φ_{NPQ} is low. However, in another survey it has
400 been reported that low Φ_{NPQ} values indicate a lower photoprotection capacity in the salt marsh
401 environmental condition (Arena et al., 2013). Photoinhibition mitigation was checked through
402 the analysis of carotenoid contents but this did not show any site effect suggesting the need of
403 further studies on individual xanthophylls characterization. Because no difference was found
404 in leaves Na^+ content it is likely that ash individuals in the meadow have evolved specific
405 mechanisms of salt retention/exclusion at the root level. Indeed, several reports have shown
406 that glycophytes may adapt to salt stress by sequestering sodium ions in their root
407 compartment (Assaha et al., 2017; Chen et al., 2018). Among the mechanisms involved, the
408 apoplastic barrier through the casparian strip seems to play a critical role in controlling Na^+
409 uptake and transport into the shoots. This is supported by the identification of suberin-forming
410 key genes as *SbKCS11* (Chen et al., 2018).

411 Given the exclusion of salt from foliar cytoplasm, it appears that the major adaptive constraint
412 of ash is water availability since the water deficit follows the growth pattern. Precisely, the
413 greater the water deficit is the more saline concentration increases thus making the water less
414 accessible to glycophytes. The concomitant fluorescence and gas exchange measurements
415 carried out in 2009 showed that the net assimilation of CO_2 was the same regardless of the
416 difference of salinity between the two sites. It is likely that the higher values of Φ_{PSII} obtained

417 in saline areas corresponds to a supplementary energy demand to sustain growth and
418 adaptation to water/salt stress. When considering the radial growth of *F. angustifolia* that
419 declines since 2011, both ATP and the anabolic coenzyme NADPH from photosynthesis
420 light-dependent reactions and the carbon assimilated are rather allocated to defense
421 processes. The tradeoffs between lignin biosynthesis and defense still remain challenging
422 although jasmonic acid and phytochrome B signalling pathway was identified as a hub that
423 coordinate plants growth and defense (Xie et al., 2018). Interestingly, differential analysis of
424 genes expressed in response to salt stress in *Fraxinus velutina* showed that the up-regulated
425 genes mainly concerned those of the biosynthetic pathway of alkaloids which are also known
426 as defense components (Yan et al., 2019).

427 5. Conclusion

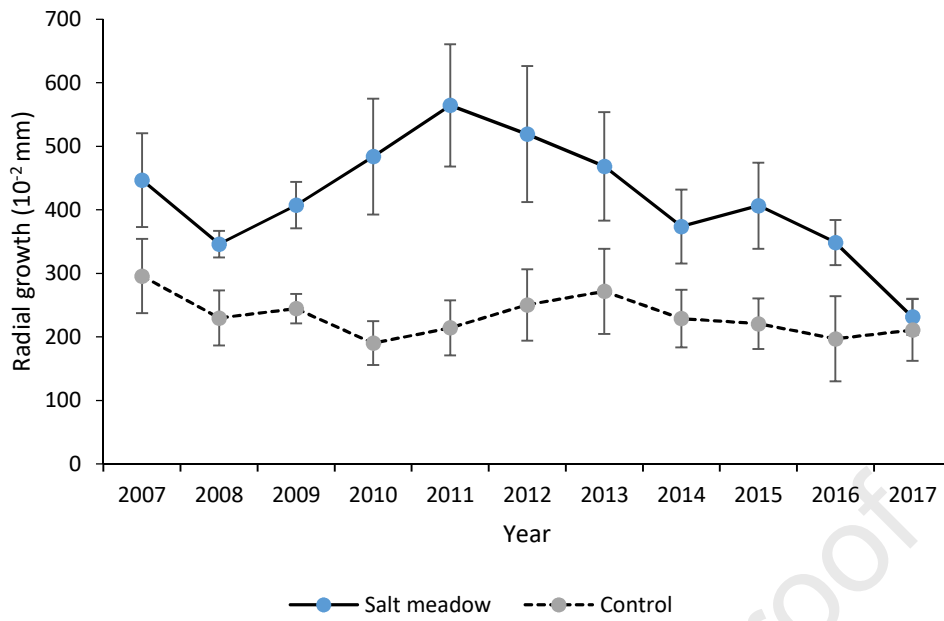

428 In conclusion, this work, carried out for 6 years between 2007 and 2016, highlighted some of
429 the adaptive mechanisms of a glycophyte in salt meadows environmental condition. Since
430 2011, a decline has been observed in the production of ash biomass in saline environments.
431 This decline seems mainly related to recurrent water deficit. In the perspective of the climate
432 change announced in the Mediterranean region, one could expect an extinction of ash in salt
433 meadows. *F. angustifolia* resistance was shown by the establishment of an efficient
434 photochemical yield both by a reduction of the fraction of the absorbed radiation which is
435 dissipated as heat and also by increasing the concentration of chlorophyll a. However, non-
436 native salt marsh species with a high tolerance to salinity and drought will be least affected by
437 the sea-level increase and drought associated to global change. Further studies are needed to
438 establish the metabolic network involved in the adaptive strategies of glycophytes in saline
439 environments.

Highlights

Adaptation of a glycophyte as *Fraxinus angustifolia* to salt meadow is determined by:

- An increase of the actual quantum yield of PSII photochemistry
- An increase of chlorophyll a contents
- A lower fraction of absorbed energy that is dissipated thermally by the ΔpH - and the xanthophyll cycle-dependent quenching in PSII (Φ_{NPQ})
- A higher photochemical quenching (qP) and the ratio Fd/Fs

Fraxinus angustifolia in salt meadow is more sensitive to global climate change. Since 2011 a decrease of the tree-rings growth was shown suggesting changes in the specific composition in these areas.
