## Abstract

CeO<sub>2</sub> sheets (CeO<sub>2</sub>-S) through hydrogen treatment (CeO<sub>2</sub>-S-H<sub>2</sub>) have been coupled with carboxylated g-C<sub>3</sub>N<sub>4</sub> (C-g-C<sub>3</sub>N<sub>4</sub>) to construct 2D/2D C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction. The ratio of Ce<sup>3+</sup>/Ce<sup>4+</sup> in CeO<sub>2</sub>-S was increased from 28.2% to 32.08% in CeO<sub>2</sub>-S-H<sub>2</sub>. Experiment results demonstrated the highest CO yields in 8 h of 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> were 2.41, 6.83 and 1.72 times of that of pure C-g-C<sub>3</sub>N<sub>4</sub>, CeO<sub>2</sub>-S and CeO<sub>2</sub>-S-H<sub>2</sub>. Heterojunction also exhibited the highest CH<sub>4</sub> yields of 11.997 μmol/g in 8 h. Interestingly, CH<sub>4</sub> yield of CeO<sub>2</sub>-S-H<sub>2</sub> was much higher than that of CeO<sub>2</sub>-S, verifying oxygen vacancy introduction can effectively enhance CH<sub>4</sub> production. In addition, 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction demonstrated the best ciprofloxacin degradation performance. It is suggested that the synergistic effects of oxygen vacancy introduction and heterojunction construction promoted charges transfer and separation.

## Keywords

Semiconductors; Nanocomposites; g-C<sub>3</sub>N<sub>4</sub>; CeO<sub>2</sub>; Oxygen vacancy

## 1. Introduction

In recent years, the construction of g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub> heterojunction with high redox capability has attracted extensive attention because of their good band matching and the reverse redox characteristics [1-3]. Among different heterostructures, 2D/2D structure has significant advantages of the enhanced light absorption, large contact area and rich active sites [4]. However, photocatalytic performance of 2D/2D g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub> heterojunction still faces great limitations mainly due to large size of 2D CeO<sub>2</sub>. The modified strategies are quite needed.

It is known that defects inevitably exist for single semiconductor material, which may cause the rearrangement of charges around them and form the localized electronic states in space and corresponding defect state energy level. When surface defects energy levels meet the thermodynamic conditions of catalytic reaction, surface defects have the advantages of providing active sites and improving charges transfer. Thus, it is expected that photocatalytic activity of 2D/2D g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub> structure can be significantly improved by introducing defects into CeO<sub>2</sub>. Herein, we report the oxygen vacancy mediated method to construct g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub> heterostructure through hydrogen treatment on CeO<sub>2</sub>. CO<sub>2</sub> reduction and organic pollutants degradation performance were investigated. The inherent catalytic mechanism of heterojunction was also discussed.

## 2 Experimental

## 2.1 Synthesis of Photocatalysts

For CeO<sub>2</sub>-S preparation, 0.75 mmol of Ce(NO<sub>3</sub>)<sub>3</sub>·6H<sub>2</sub>O, 0.6 mL of acetic acid and 5.25 mmol of hexamethylenetetramine were firstly dissolved in 15 mL of deionized water. Then, the solutions were hydrothermally treated at 140 °C for 9 h to obtain precipitates, which were further annealed in muffle furnace at 500 °C for 2 h. As-obtained CeO<sub>2</sub>-S was light yellow. To regulate surface oxygen vacancy, CeO<sub>2</sub>-S was further treated in gas mixtures of hydrogen (5%) and argon (95%) at 500 °C for 2 h. The colour of CeO<sub>2</sub>-S-H<sub>2</sub> was gray white.

C-g-C<sub>3</sub>N<sub>4</sub> was synthesized by refluxing g-C<sub>3</sub>N<sub>4</sub> bulks in HNO<sub>3</sub> solution [5]. For C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> preparation, a certain amount of C-g-C<sub>3</sub>N<sub>4</sub> and CeO<sub>2</sub>-S-H<sub>2</sub> with total mass of 0.5 g were firstly mixed. C-g-C<sub>3</sub>N<sub>4</sub> content was accounted for 20%, 40%, 60% and 80% respectively. Secondly, solid mixtures were dispersed in 50 mL of methanol solution by ultrasonication and magnetic stirring. Finally, solid powderz were calcined at 150 °C for 4 h. Specific preparation process is shown in Scheme S1. Characterization techniques and photoelectrochemical measurement were shown in supplementary materials.

## 2.2 Photocatalytic Test

CO<sub>2</sub> reduction was carried out in a 120 mL of cylindrical glassware reactor, in which 50 mg of catalyst powders was firstly placed inside. Before reaction, high purity CO<sub>2</sub> (99.99%) gas flushed the reactor. 2 mL of deionized water was injected into the reactor as reducing agent. A 300 W Xe lamp ( $\lambda > 400$  nm) was used as light source. Target products were analysed using gas chromatography with FID detector. For ciprofloxacin (CIP) degradation, 50 mg of catalyst was dispersed in 100 mL of CIP aqueous solution (10 mg/L). Typically, suspensions were magnetically stirred in dark for 30 min. Afterwards, it was irradiated by 300 W Xe lamp ( $\lambda > 400$  nm). CIP concentration was analysed by UV-visible spectrophotometer (Shimadzu UV-2600, Japan).

## 3 Results and Discussion

Fig.1 shows the morphologies of photocatalysts. Typical diffraction peaks of both g-C<sub>3</sub>N<sub>4</sub> and CeO<sub>2</sub> phases have been observed in patterns of C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> (Fig.S1). C-g-C<sub>3</sub>N<sub>4</sub> morphology mainly presents nanosheets and nanoparticles (Fig.1a), while CeO<sub>2</sub>-S is composed of sheets with diameter of about 200-500 nm (Fig.1b). A layer-to-layer stack-like sandwich structure is observed for 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> (Fig.1c). It should be noted that hydrogen treatment has little effect on CeO<sub>2</sub>-S morphology. TEM image of 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> shows that CeO<sub>2</sub>-S-H<sub>2</sub> sheets are evenly

distributed on C-g-C<sub>3</sub>N<sub>4</sub> surface, and a 2D/2D stacked layered structure is formed (Fig.1d). High-resolution TEM image displays (Fig.1e) the lattice spacing of CeO<sub>2</sub>-S-H<sub>2</sub> is 0.19 nm, which corresponds to (110) crystal plane. These results demonstrate C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> was successfully prepared. Elements mapping of 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> (Fig.1f-Fig.1j) displays C, N, Ce, and O elements are uniformly distributed, which further ensures that a 2D/2D structure is constructed.

Fig.1 SEM images of C-g-C<sub>3</sub>N<sub>4</sub> (a), CeO<sub>2</sub>-S (b), and 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> (c). TEM images (d, e) and element mapping images of 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> ( f, g, h, i, j)

To verify the effects of hydrogen treatment on surface defects, XPS spectra, TG analysis and Raman spectra were performed. As indicated in Fig.2a, C, N, O and Ce elements have been observed in the survey scanning spectra. Fig.2b shows high-resolution Ce 3d spectra. Ce 3d orbitals of CeO<sub>2</sub>-S can be fitted into 8 peaks. Binding energies centered at 883.93 eV and 902.28 eV are due to Ce<sup>3+</sup> states, and the other binding energy peaks are characteristics of Ce<sup>4+</sup> states in CeO<sub>2</sub> [6]. The ratio of Ce<sup>3+</sup> to Ce<sup>4+</sup> in CeO<sub>2</sub>-S is 28.2%, while it is 32.08% in CeO<sub>2</sub>-S-H<sub>2</sub>, which shows that oxygen vacancy content increases after hydrogen treatment. For CeO<sub>2</sub>-S-H<sub>2</sub> and 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub>, the position of Ce 3d peak has slightly changed due to the varied chemical environment. The other high-resolution XPS spectra of C1s, N1s and O1s can be found in Fig.S2. In Fig.2c, pristine C-g-C<sub>3</sub>N<sub>4</sub> sample has mass loss at about 340 °C due to carboxyl groups decomposition, which is consistent with FTIR results in Fig.S3. Mass loss of CeO<sub>2</sub>-S is relatively higher than that of CeO<sub>2</sub>-S-H<sub>2</sub> due to oxygen escaping from lattice at

high temperature. Compared with pure C-g-C<sub>3</sub>N<sub>4</sub>, the introduction of CeO<sub>2</sub>-S-H<sub>2</sub> has resulted in decomposition temperature decrease for C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction. Fig.2d shows Raman spectra of CeO<sub>2</sub>-S and CeO<sub>2</sub>-S-H<sub>2</sub>. The sharp characteristic peak at 460 cm<sup>-1</sup> corresponds to F2g vibration mode (Ce-O), while the weak peak at 600 cm<sup>-1</sup> is caused by oxygen vacancy [7]. The peak intensity of CeO<sub>2</sub>-S-H<sub>2</sub> at 600 cm<sup>-1</sup> is higher than that of CeO<sub>2</sub>-S, which further proves that hydrogen treatment has led to the increase of oxygen vacancy in CeO<sub>2</sub> lattice.

Fig.2 Survey scanning spectra (a) and high-resolution Ce 3d spectra (b) of CeO<sub>2</sub>-S, CeO<sub>2</sub>-S-H<sub>2</sub>, and 60% C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub>. TG curves of C-g-C<sub>3</sub>N<sub>4</sub>, CeO<sub>2</sub>-S, CeO<sub>2</sub>-S-H<sub>2</sub> and C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunctions (c) and Raman spectra of CeO<sub>2</sub>-S and CeO<sub>2</sub>-S-H<sub>2</sub> samples (d)

Fig.3a shows CIP degradation curves. CIP degradation efficiency of 60% C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> reaches 78.5% within 120 min, which are 3 times, 7.48 times and 2.34 times of that of pristine C-g-C<sub>3</sub>N<sub>4</sub> (26.1%), CeO<sub>2</sub>-S (10.5%) and CeO<sub>2</sub>-S-H<sub>2</sub> (33.5%). Degradation rate constant of 60% C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> is 5.027, 15.347 and 3.916 times of that of C-g-C<sub>3</sub>N<sub>4</sub>, CeO<sub>2</sub>-S and CeO<sub>2</sub>-S-H<sub>2</sub> (Fig.3b). Fig.3c and 3d show CO and CH<sub>4</sub> yields on different photocatalysts. CO yields on C-g-C<sub>3</sub>N<sub>4</sub>, CeO<sub>2</sub>-S, CeO<sub>2</sub>-S-H<sub>2</sub> and 60% C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> are 7.904 μmol/g, 2.785 μmol/g, 11.040 μmol/g and 19.032 μmol/g, while CH<sub>4</sub> yields are 0.261 μmol/g, 5.139 μmol/g, 11.211 μmol/g and

11.997  $\mu\text{mol/g}$ . Especially,  $\text{CO}_2$  reduction on  $\text{CeO}_2\text{-S-H}_2$  is much better than  $\text{CeO}_2\text{-S}$ , which may be related to the increase of oxygen vacancy content. Interestingly,  $\text{CH}_4$  yields on  $\text{C-g-C}_3\text{N}_4$  is negligible. However, 60% $\text{C-g-C}_3\text{N}_4/\text{CeO}_2\text{-S-H}_2$  exhibits the highest  $\text{CH}_4$  yields in 8 h, demonstrating heterojunction has advantages of both single components.

Fig.3 CIP degradation curves (a), first-order reaction kinetics curves (b), CO yields (c) and  $\text{CH}_4$  yields (d) using  $\text{C-g-C}_3\text{N}_4$ ,  $\text{CeO}_2\text{-S}$ ,  $\text{CeO}_2\text{-S-H}_2$  and  $\text{C-g-C}_3\text{N}_4/\text{CeO}_2\text{-S-H}_2$  samples

Charges transfer and separation is of significance for photocatalytic activity enhancement. In Fig.4a, 60% $\text{C-g-C}_3\text{N}_4/\text{CeO}_2\text{-S-H}_2$  heterojunction displays the strongest photocurrent response. Accordingly, its semicircular diameter of Nyquist curve is the smallest as depicted in Fig.S4. Similarly, it shows the lowest photoluminescence intensity (Fig.4b). The corresponding transient PL was also depicted in Fig.S5. All these results demonstrate that heterojunction has enhanced charges separation efficiency. More charges will participate in the reaction. In Fig.4c, trapping experiments were carried out using 60% $\text{C-g-C}_3\text{N}_4/\text{CeO}_2\text{-S-H}_2$  as photocatalyst for CIP degradation. 1 mmol potassium iodide (KI), 1 mmol isopropanol (IPA) and nitrogen ( $\text{N}_2$ ) were used as  $\text{h}^+$ ,  $\bullet\text{OH}$  and  $\bullet\text{O}_2^-$  scavengers. It can be observed that  $\bullet\text{OH}$  is the most important active species involved in CIP degradation.  $\text{h}^+$  is one of the major active species, which can seriously suppress heterojunction activity. However,  $\bullet\text{O}_2^-$  is not a major

active species.

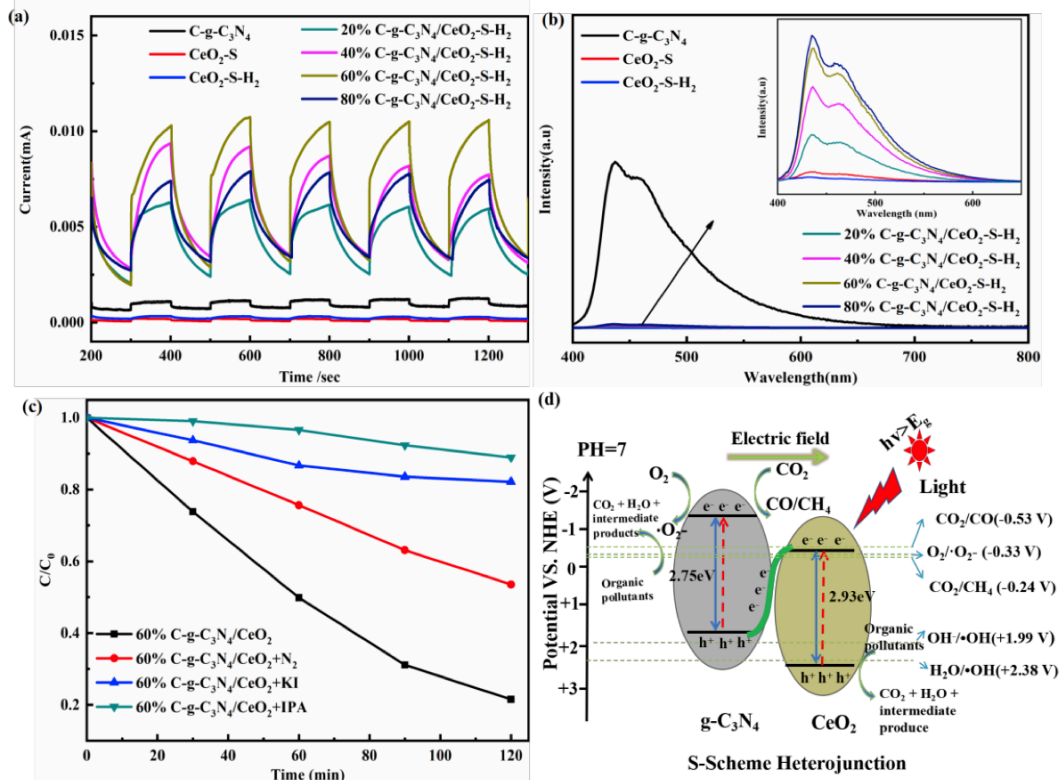

Fig.4 Transient photocurrent responses (a) and PL spectra of C-g-C<sub>3</sub>N<sub>4</sub>, CeO<sub>2</sub>-S, CeO<sub>2</sub>-S-H<sub>2</sub>,

C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction. Trapping experiments of CIP degradation by

60% C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction (c) and proposed photocatalytic mechanism

Band gaps of C-g-C<sub>3</sub>N<sub>4</sub> and CeO<sub>2</sub>-S-H<sub>2</sub> have been calculated as 2.75 eV and 2.93 eV from UV-Vis DRS spectra (shown in Fig.S6). According to the Mulliken's electronegativity theory formula [8], VB and CB positions of C-g-C<sub>3</sub>N<sub>4</sub> and CeO<sub>2</sub>-S-H<sub>2</sub> are +1.615 eV, -1.135 eV and +2.535 eV, -0.395 eV. As O<sub>2</sub>/•O<sub>2</sub><sup>-</sup> reduction potential is -0.33 V (NHE, pH=7), C-g-C<sub>3</sub>N<sub>4</sub> is more favorable for •O<sub>2</sub><sup>-</sup> radicals formation due to its more negative CB potential. On the other hand, VB potential of CeO<sub>2</sub>-S-H<sub>2</sub> is more positive than H<sub>2</sub>O/•OH (+2.38 V vs. NHE) and OH<sup>-</sup>/•OH (+1.99 V vs. NHE). Therefore, the photogenerated h<sup>+</sup> can react with H<sub>2</sub>O molecules or OH<sup>-</sup> to produce •OH radicals. In contrast, C-g-C<sub>3</sub>N<sub>4</sub> cannot generate •OH radicals under the same conditions. Thus, an S-scheme photocatalytic mechanism is proposed in Fig.4d [2, 9]. For CO<sub>2</sub> reduction, CB potential of C-g-C<sub>3</sub>N<sub>4</sub> is more negative than the potential required for CO/CO<sub>2</sub> (-0.53 V) and CH<sub>4</sub>/CO<sub>2</sub> (-0.24 V) conversions. Therefore, it is easy to reduce CO<sub>2</sub> to CO or CH<sub>4</sub>. In CO<sub>2</sub> reduction process, H<sub>2</sub>O is firstly oxidized to H<sup>+</sup> and O<sub>2</sub> by holes. Meanwhile, CO<sub>2</sub> molecules are reduced to CO and CH<sub>4</sub> with the aid of H<sup>+</sup> and electrons. It should be

1 noted that oxygen vacancy in CeO<sub>2</sub>-S-H<sub>2</sub> can be used as electrons capture centers. As a result, electrons  
2 enrichment improves the kinetic conditions of CO<sub>2</sub> reduction, especially for CH<sub>4</sub> production. At the  
3 same time, oxygen vacancy can adsorb and activate CO<sub>2</sub> molecules, thus 2D/2D C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub>  
4 heterojunction exhibits high CO and CH<sub>4</sub> yields in contrast to single components. In addition, Ce<sup>4+</sup> in  
5 CeO<sub>2</sub>-S-H<sub>2</sub> can enhance electrons capture to form Ce<sup>3+</sup>, so as to promote charges separation and  
6 significantly improve photocatalytic activity.  
7  
8  
9

#### 10 11 12 **4 Conclusions**

13  
14 In conclusion, C-g-C<sub>3</sub>N<sub>4</sub> have been compounded with hydrogen treated flaky CeO<sub>2</sub>-S-H<sub>2</sub> to  
15 construct 2D/2D C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> heterojunction. In contrast to pure components,  
16 60%C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> exhibited the highest activity for CIP degradation and CO<sub>2</sub> reduction.  
17 Radicals trapping experiments showed •OH and h<sup>+</sup> were the two major active species in CIP  
18 degradation. The introduction of oxygen vacancy in CeO<sub>2</sub>-S-H<sub>2</sub> has greatly enhanced CH<sub>4</sub> yields as it  
19 can be used as electron capture centers and promoted charges separation efficiency. Possible S-scheme  
20 mechanism of C-g-C<sub>3</sub>N<sub>4</sub>/CeO<sub>2</sub>-S-H<sub>2</sub> was proposed.
